

Life under the laser

August 22 2008

Researchers at The University of Nottingham have developed a unique technology that will allow scientists to look at microscopic activity within the body's chemical messenger system for the very first time, live as it happens.

The cutting edge laser technology has helped to attract £1.3 million from the MRC (Medical Research Council) for a five-year project that will offer a new insight into the tiny world of activity taking place within single cells and could contribute to the design of new drugs to treat human diseases such as asthma and arthritis with fewer side effects.

The team, involving scientists from the University's Schools of Biomedical Science (Professor Steve Hill and Dr Steve Briddon) and Pharmacy (Dr Barrie Kellam), is concentrating on a type of specialised docking site (receptor) on the surface of a cell that recognises and responds to a natural chemical within the body called adenosine.

These A3-adenosine receptors work within the body by binding with proteins to cause a response within cells and are found in very tiny and highly specialised area of a cell membrane called microdomains. Microdomains contain a collection of different molecules that are involved in telling the cell how to respond to drugs or hormones.

It is believed that these receptors play an important role in inflammation within the body and knowing more about how they operate could inform the future development of anti-inflammatory drugs that target just those receptors in the relevant microdomain of the cell, without influencing

the same receptors in other areas of the cell. However, scientists have never before been able to look in detail at their activity within these tiny microscopic regions of a living cell.

The Nottingham researchers have solved this problem by creating novel drug molecules which have fluorescent labels attached. Using a cutting edge laser technology called fluorescence correlation spectroscopy, the fluorescent drug molecules can be detected as they glow under the laser beam of a highly sensitive microscope. This allows their binding to the receptor to be followed for the first time in real time at the single molecule level.

Leading the project, Professor Steve Hill in the School of Biomedical Sciences said: "These microdomains are so tiny you could fit five million on them on a full stop. There are 10,000 receptors on each cell, and we are able to follow how single drug molecules bind to individual receptors in these specialised microdomains.

"What makes this single molecule laser technique unique is that we are looking at them in real time on a living cell. Other techniques that investigate how drugs bind to their receptors require many millions of cells to get a big enough signal and this normally involves destroying the cells in the process"

The researchers will be using donated blood as a source of A3-receptors in specialised human blood cells (neutrophils) that have important roles during inflammation.

Different types of adenosine receptors are found all over the body and can exist in different areas of the cell membrane and have different properties. Scientists hope that eventually the new technology could also be used to unlock the secrets of the role they play in a whole host of human diseases.

The fluorescent molecules developed as part of the research project will also be useful in drug screening programmes and The University of Nottingham will be making these fluorescent drugs available to the wider scientific community through its links with its spin-out company CellAura Technologies Ltd.
