

New pathway identified in Parkinson's through brain imaging

September 13 2010

A new study led by researchers at Columbia University Medical Center has identified a novel molecular pathway underlying Parkinson's disease and points to existing drugs which may be able to slow progression of the disease.

The pathway involved proteins - known as polyamines - that were found to be responsible for the increase in build-up of other toxic proteins in neurons, which causes the neurons to malfunction and, eventually, die. Though high levels of polyamines have been found previously in patients with Parkinson's, the new study - which appeared in an early online edition of [Proceedings of the National Academy of Sciences](#) - is the first to identify a mechanism for why polyamines are elevated in the first place and how polyamines mediate the disease.

The researchers also demonstrated in a [mouse model](#) of Parkinson's disease that polyamine-lowering drugs had a protective effect.

"The most exciting thing about the finding is that it opens up the possibility of using a whole class of drugs that is already available," says Scott A. Small, MD, the senior author of the study and Herbert Irving Associate Professor of Neurology in the Sergievsky Center and in the Taub Institute for Research on Alzheimer's Disease and the Aging Brain at Columbia University Medical Center. "Additionally, since polyamines can be found in blood and spinal fluid, this may lead to a test that could be used for early detection of Parkinson's."

Currently, treatments for Parkinson's can help alleviate some of the disease's symptoms, but they cannot prevent the build-up of toxic proteins and the death of neurons caused by the disease. When polyamines were scrutinized decades ago as a potential therapy against cancer, polyamine-lowering drugs were tested and have completed the Phase 1 and 2 safety stages of [clinical trials](#). However, whether the drugs can pass through the blood-brain barrier remains to be determined and further testing will be needed. If the drugs can reduce the level of polyamines in the brain, they may pave the way for a Parkinson's treatment that can slow the disease's progression.

"This research has the potential to progress quickly," says James Beck, PhD, director of research programs at the Parkinson's Disease Foundation, which helped support the research. "Equally exciting are the new avenues of research this study opens, hopefully leading to better treatments for Parkinson's Disease down the road."

Though many cellular defects have been found to cause rare, inherited forms of Parkinson's disease, most cases of Parkinson's are caused by unknown changes inside the brain's neurons.

The researchers used a wide variety of scientific techniques to search for still unidentified defects in the brain. The suite of techniques - which started with high resolution brain imaging - has been used to reveal previously unknown molecules in the brain that worsen Alzheimer's disease.

Imaging Reveals Brainstem Defect in Parkinson's Patients

The success of the technique depends on identifying regions of the brain affected by the disease and comparing them to unaffected regions.

Using high resolution functional magnetic resonance imaging (fMRI), Nicole Lewandowski, PhD, who is currently a post-doctoral research scientist in Dr. Small's lab, identified such regions in the brainstem of patients with Parkinson's. The scans showed that one region of the brainstem was consistently less active in these patients than in healthy control subjects. Also revealed in the scans was a neighboring region that was unaffected by the disease.

Next, using brain tissue from deceased patients with Parkinson's, the researchers looked for proteins that could potentially explain the brainstem imaging differences.

"One such protein we found, called SAT1, stood out," said Dr. Small. "Because SAT1 is known as an enzyme that helps break down polyamines, and previous research had shown that Parkinson's patients have high levels of polyamines in their brains, we hypothesized that SAT1 and polyamines are involved in the development of Parkinson's disease."

Three Experiments Confirm Polyamines Are Pathogenic

To validate the finding, three separate studies - in yeast, mice, and people - were performed.

The yeast studies revealed that polyamines promote the accumulation of a toxic Parkinson's-causing protein in living cells, and not just in test tubes, as was known from previous research. Conducted by Gregory Petsko, PhD, the Gyula and Katica Tauber Professor of Biochemistry and Chemistry and Chair of Biochemistry at Brandeis University and Dagmar Ringe, PhD, the Harold and Bernice Davis Professor of Aging and Neurodegenerative Disease Research at Brandeis, the new studies

found that yeast cells, engineered to produce the toxic Parkinson's protein, die more quickly in the presence of increasing polyamine levels. Furthermore, in a screen conducted for mediators of Parkinson's toxins in the lab of Susan Linquist, PhD, professor of biology in the Whitehead Institute for Biomedical Research and Howard Hughes Medical Institute at MIT, other genes related to polyamine transport were identified.

In the mice studies, a link was established among SAT1, polyamines, and Parkinson's toxins in a mammalian brain. These experiments also revealed that drugs that target SAT1 may be able to slow down the progression of Parkinson's disease. Using drugs that increase SAT1 activity and therefore lower polyamine levels, researchers in the lab of Eliezer Masliah, MD, professor of neurosciences and pathology at the UC San Diego School of Medicine, found a decrease in Parkinson's toxins and the damage which they cause within brain regions affected by the disease.

Genetic studies in patients with Parkinson's provided further evidence that polyamines may help drive Parkinson's disease in people. After examining the SAT1 gene in nearly 100 patients with Parkinson's and additional genotyping in a further ~800 subjects (389 PD patients and 408 controls), enrolled in the Genetic Epidemiology of [Parkinson's disease](#) study at CUMC, Columbia geneticist Lorraine Clark, PhD, assistant professor of clinical pathology and cell biology, together with Karen Marder, MD, MPH, who is the Sally Kerlin Professor of [Neurology](#) in the Sergievsky Center and in the Taub Institute, uncovered a novel genetic variant that was found exclusively in the study's patients with Parkinson's but not in controls.

"Even though the variant was rare in patients with Parkinson's, finding it was surprising and further strengthens the possibility that defects in the polyamine pathway help to trigger the disease," said Dr. Small.

Dr. Small is now testing current polyamine-lowering drugs to see if the compounds can pass through the blood-brain barrier, or if they can be altered to do so. Drugs that pass through the blood-brain barrier can be administered more easily (e.g., they can be taken by mouth) instead of directly infusing them into the brain.
