

New lab model of Alzheimer's disease will help research

February 16 2012

(Medical Xpress) -- A new way of studying Alzheimer's disease in the laboratory has been developed by scientists at the Wellcome Trust and Cancer Research UK Gurdon Institute in Cambridge and will help researchers understand more clearly how the disease progresses in real life.

The researchers took [stem cells](#) created from skin cells donated by volunteers and used them to generate populations of nerve cells that behave just like the cells in a human brain. This model could be used both to follow how Alzheimer's disease starts and progresses in people and to test and develop potential new treatments for the disease.

Crucially, the cells used were from volunteers with Down's syndrome. People with Down's syndrome are at a higher risk of developing Alzheimer's disease and are often diagnosed with it in middle age;

consequently, by using their stem cells, the progression of Alzheimer's disease can be tracked faster than by using cells from the general population. In the lab, the model develops disease over a matter of months rather than the years or decades that it takes in real life.

Animal models have been used effectively for research into Alzheimer's disease, but it is difficult to reproduce every aspect of the disease. Using human cells, the new model develops all the hallmarks of Alzheimer's disease as it appears in patients' brains studied post-mortem: it shows the same plaques of a protein called amyloid, as well as 'tangles' of another protein called tau, and many other characteristic features.

Amyloid is derived from a precursor called APP (amyloid precursor protein), which is controlled by a gene on chromosome 21. People with Down's syndrome have an extra copy of chromosome 21, which is why they are at greater risk of developing Alzheimer's disease and of developing it at an earlier age than other people. This also explains why using stem cells from people with Down's syndrome contributes to the increased rate at which the new model progresses in the lab.

Dr Rick Livesey, who led the study (which was published yesterday in *Science Translational Medicine*), said: "One of the biggest challenges facing dementia researchers at the moment is a lack of good ways to track the disease over time. By using stem cells donated from people with Down's syndrome, we have been able to track how the disease develops over a shorter time period than has been possible in the past.

"What is promising about this stem cell technique is that we can create functioning human cortex cells in a dish, allowing us to more closely model what is happening in our brains. Not only this, but our new [model](#) shows many of the characteristic features of human [Alzheimer's disease](#) and will allow us to test new treatments more easily."
