

Two-pronged immune cell approach could lead to universal shot against flu

March 14 2013

Seasonal epidemics of influenza result in nearly 36,000 deaths annually in the United States, according to the Centers for Disease Control. Current vaccines against the influenza virus elicit an antibody response specific for proteins on the outside of the virus, specifically the hemagglutinin (HA) protein.

Yearly vaccines are made by growing the [flu virus](#) in eggs. The viral envelope proteins, including HA, are cleaved off and used as the vaccine, but vary from year to year, depending on what [flu strains](#) are prevalent. However, high [mutation rates](#) in envelope HA proteins result in the emergence of new viral types each year, which elude neutralization by preexisting antibodies in the body (specifically the HA proteins' specific receptor binding sites that are the targets of neutralizing antibodies). On the other hand, other immune cell types are capable of mediating protection through recognition of other, more conserved parts of HAs or highly conserved internal proteins in the influenza virus.

E. John Wherry, PhD, associate professor of Microbiology and director of the Institute for Immunology at the Perelman School of Medicine, University of Pennsylvania, and colleagues, report in *PLOS Pathogens* that [influenza virus](#)-specific CD8+ T cells or virus-specific non-neutralizing antibodies are each relatively ineffective at conferring [protective immunity](#) alone. But, when combined, the virus-specific CD8 T cells and non-neutralizing antibodies cooperatively elicit robust protective immunity.

This synergistic improvement in protective immunity is dependent, at least in part, on other [immune cells](#)—lung macrophages and phagocytes. An implication of this work is that immune responses targeting parts of the virus that are not highly variable can be combined for effective protection.

"The two-pronged approach is synergistic, so by enlisting two suboptimal vaccine approaches, we achieved a better effect than each alone in an experimental model," says Wherry. "Now, we are rethinking past approaches and looking for ways to combine T-cell vaccines and antibody vaccines to make a more effective combined vaccine."

"Overall, our studies suggest that an influenza vaccine capable of eliciting both CD8+ T cells and antibodies specific for highly conserved influenza proteins may be able to provide protection in humans, and act as the basis for a potential 'universal' vaccine," says Wherry.

These results suggest a novel strategy that could potentially form a primary component of a universal influenza vaccine capable of providing long-lasting protection.
