

# Biomarker identification may lead to new noninvasive test for colorectal cancer detection

June 7 2013

---

The average 5-year survival for colorectal cancer (CRC) is less than 10% if metastasis occurs, but can reach 90% if detected early. A new non-invasive test has been developed that measures methylation of the SDC2 gene in tissues and blood sera. This test detected 87% of all stages of colorectal cancer cases (sensitivity) without significant difference between early and advanced stages, while correctly identifying 95% of disease-free patients (specificity). The results are published in the July issue of *The Journal of Molecular Diagnostics*.

According to the US Centers for Disease Control and Prevention, CRC is the second leading cancer killer in the US affecting both men and women. In 2009, close to 137,000 people in the US were diagnosed with CRC, with close to a 40% mortality rate.

There are other screening choices for CRC, including [fecal occult blood testing \(FOBT\)](#), fecal immunochemical testing, and colonoscopy. Colonoscopy is the gold standard of CRC screening, but patient resistance – mostly due to the unpleasant preparation – has curbed widespread adoption. FOBT is non-invasive but has limited sensitivity, particularly for early disease. A sensitive and specific non-invasive test using blood or stool could to be a more preferable option with the potential of saving many lives.

In their search for a [biomarker](#) that could be used for the early detection

of CRC, investigators from Genomictree, Inc. and Yonsei University College of Medicine in Seoul, South Korea, performed DNA microarray analysis coupled with enriched methylated DNA using tissues from primary tumors and non-tumor tissues from 12 CRC patients. After step-wise filtering, they found a set of genes that were highly methylated across all of the CRC tumors. Ultimately they identified one gene, SDC2, which encodes the membrane syndecan-2 protein, a protein that is known to participate in [cell proliferation](#), [cell migration](#), and is expressed in colon [mesenchymal cells](#). The methylation level of target region of SDC2 assessed in tumor tissue was found to be significantly higher than that from paired adjacent non-tumor tissue.

The next step was to clinically validate the biomarker by analyzing SDC2 methylation levels in primary tumors and paired-adjacent non-tumor tissue samples from 133 CRC patients. Investigators found that in the transcriptional regulatory region of the SDC2 gene, tumor samples showed significantly higher levels of methylation than the control samples. SDC2 methylation positivity ranged from 92.9% to 100% when samples were stratified according to stages of cancer.

Further, investigators found that the SDC2 biomarker could be measured in serum samples from CRC patients and healthy individuals. "The SDC2 methylation test was able to detect 92% for detection of stage I cancer patients indicating that SDC2 is suitable for early detection of CRC where therapeutic interventions have the greatest likelihood of curing the patient from the disease," says first author TaeJeong Oh, PhD.

The authors suggest that the SDC2 methylation test they describe could possibly be used as an alternative to or in conjunction with [colonoscopy](#). It could also be used to monitor cancer progression and treatment. Dr. Sungwhan An, corresponding author and CEO of Genomictree, Inc., commented: "We are very excited with this result using a small amount of serum DNA from less than 1ml of blood. I believe a greater volume

of blood will further improve the clinical performance of this test. We are currently preparing another set of clinical validation studies evaluating SDC2 methylation in serum DNA from patients with early adenoma." In future research the authors will explore whether this biomarker is specific to CRC or universal among other cancers.
