

History of teenage acne tied to increased risk for melanoma

May 18 2015

(HealthDay)—Having a history of teenage acne is associated with an increased risk of melanoma, independent of known risk factors, according to a study published in the May 15 issue of *Cancer*.

Mingfeng Zhang, M.D., Ph.D., from the Brigham and Women's Hospital in Boston, and colleagues followed 99,128 female nurses in the Nurses' Health Study II cohort for 20 years to examine the risks of eight specific cancers for women with a history of severe teenage cancer.

The researchers found that among women with a history of severe teenage acne, there was an increased relative risk for melanoma (multivariate-adjusted hazard ratio, 1.44) after full adjustment for previous known [risk factors](#) for each cancer. This association was replicated in an independent melanoma case-control study involving 930

cases and 1,026 controls (multivariable-adjusted odds ratio, 1.27). In both studies, the likelihood of having moles was increased for those with teenage acne (P cohort study and $P = 0.004$ in the case-control study).

"In summary, we identify a history of teenage acne as a novel risk factor for [melanoma](#) independent of previously identified risk factors," the authors write. "Our findings support a need for continued investigation of the relationship between acne and hormone-related cancers."
