Researchers at the Babraham Institute and University of Massachusetts Medical School in the United States have developed a new model to study motor neuron degeneration and have used this to identify three genes involved in the neurodegeneration process. These findings could have relevance for understanding the progression of amyotrophic lateral sclerosis (ALS) and other forms of motor neuron disease (MND). ALS is the most common form of adult-onset motor neuron disease and kills over 1,200 people a year in the UK.

The researchers developed a new model to study [neurodegeneration](#) in the common fruit fly (*Drosophila melanogaster*). In contrast to other methods used to study neurodegeneration such as looking at changes in eye morphology or studying larval stages, the researchers focused their attention on studying the neurons in a fruit fly's leg. Using the leg allows the detailed study of a single motor neuron, the nerve cell involved in passing signals from the brain to a muscle. Compared to studying larval stages, the model also permits genuine ageing studies as changes in neurons can be observed in flies of different ages. The adult fruit fly can live for over two months in the lab. Furthermore, the fruit fly also provides the benefits of rapid development (ten days from egg to adult), allowing high-throughput genetic screens.

As described online in *Current Biology*, the researchers used the [new model](#) to study the role of a protein central to the development of ALS called TDP-43. Specifically overexpressing TDP-43 in fly legs caused neurodegeneration. Exposing these flies to a mutagen and looking for offspring showing reduced neurodegeneration allowed the researchers to identify three genes implicated in mediating the effects of TDP-43. One, shaggy/GSK3, was already known to be associated with the neurodegeneration process but two of them, hat-trick and xmas-2, were new discoveries.

Dr Jemeen Sreedharan, Senior Research Fellow in the signalling research

programme at the Babraham Institute and lead author on the paper said: "We're extremely excited about our new approach to using the power of *Drosophila* genetics. Never before has anyone been able to study adult neurodegeneration in an invertebrate system with such ease. By modelling the earliest stages of ALS (synaptic and axon degeneration) we have identified three intriguing genetic suppressors of degeneration in the fly and are now validating these results in mammalian neuronal cultures. We hope that by using the fly we can accelerate progress towards eventually developing therapies for ALS and other neurodegenerative diseases."
