

Antibiotic-infused implants designed to help faces heal

December 18 2015

A scanning electron microscope image shows the outer surface of a porous PMMA space maintainer that has been cut to fit the dimensions of a jawbone

defect. Scientists at Rice University have developed a method to infuse the porous material with time-released antibiotics that protect patients from infection while they heal. Credit: The Mikos Research Group/Rice University

Rice University researchers developing temporary implants for facial reconstruction are incorporating a unique way to deliver time-released antibiotics to ward off infection while a patient heals.

The Rice laboratory of bioengineer Antonios Mikos develops materials to help repair severe craniofacial injuries from trauma or pathological defects like tumor removal. The lab's specialized plastic space maintainers are designed to keep a pocket for new bone open while the overlying soft tissue heals. In later surgery, the implant is removed to make way for reconstruction of the bone.

In the latest advance, porous polymethylmethacrylate (PMMA) implants are filled with a gel that leaches its protective antibiotic contents to surrounding tissue, which protects the tissue from infection for several weeks.

The project is the subject of a paper that appeared this week in the Royal Society of Chemistry journal *Biomaterials Science*.

"Infection is an important problem that needs to be considered with medical devices because bacteria can prevent the body from being able to heal," Mikos said. "If the infection gets too severe, it can even cause tissues that were previously healthy to die."

The researchers led by Rice alumnus Paschalia (Lina) Mountziaris noted that infections from the external environment and from neighboring structures such as the nasal passages, the sinuses and the mouth can

attack vulnerable tissue. Several studies have indicated wound infections from gunshot injuries to the face are common, they noted.

Soldiers are at particular risk, said Mikos, as battlefield injuries are often prone to infection from multidrug-resistant species of bacteria that invade between the time of injury and treatment.

Labs at Rice and elsewhere have experimented with porous implants but found they are susceptible to invasion by infectious bacteria. The Mikos lab's solution is to fill the pores at the point of care with a thermogel that infuses the spacer as a liquid and turns into a gel when exposed to body heat.

The thermogel itself is special. It consists of a block copolymer, a self-assembling combination of two polymers that is also under investigation for the controlled release of chemotherapy drugs.

"Block copolymers can offer a lot of benefits since they are designed to take advantage of the strengths of individual polymers," Mikos said.

"The [block copolymer](#) we used for our study was designed to be able to take on water, become a gel at body temperature and slowly degrade over the course of implantation."

Porous implants have been tested in humans, but PMMA with thermogel has not, Mikos said. In experiments, the Rice lab infused the gel with colistin, a last-resort antibiotic with strong side effects. He said the PMMA and copolymer combination enabled tight control of its release without disrupting its antibacterial activity. In testing, the implants initially released a burst of the antibiotic through diffusion. Over time, degradation of the copolymer would continue to release lesser amounts of the drug for up to 28 days.

Mikos said the thermogel can be customized at the time of implantation

with the appropriate antibiotics, which also affect the rate and duration of release, before infusion into the prefabricated spacer.
