

Adult brain prunes branched connections of new neurons

May 2 2016

A new Salk study is the first to closely follow the development of new neurons in the adult brain, giving insight into neurodevelopmental disorders such as autism and schizophrenia. By genetically engineering new neurons to fluoresce green, researchers were able to see when the new cells grew and branched surrounded by other cell nuclei (blue) in the brain. When tweaking its architecture, the adult brain works like a sculptor—starting with more than it needs so it can carve away the excess to achieve the perfect design. That's the conclusion of a new study that tracked developing cells in an adult mouse brain in real time.

New [brain cells](#) began with a period of overgrowth, sending out a plethora of neuronal branches, before the brain pruned back the connections. The observation, described May 2, 2016 in *Nature Neuroscience*, suggests that new cells in the [adult brain](#) have more in common with those in the embryonic brain than scientists previously thought and could have implications for understanding diseases including autism, intellectual disabilities and schizophrenia.

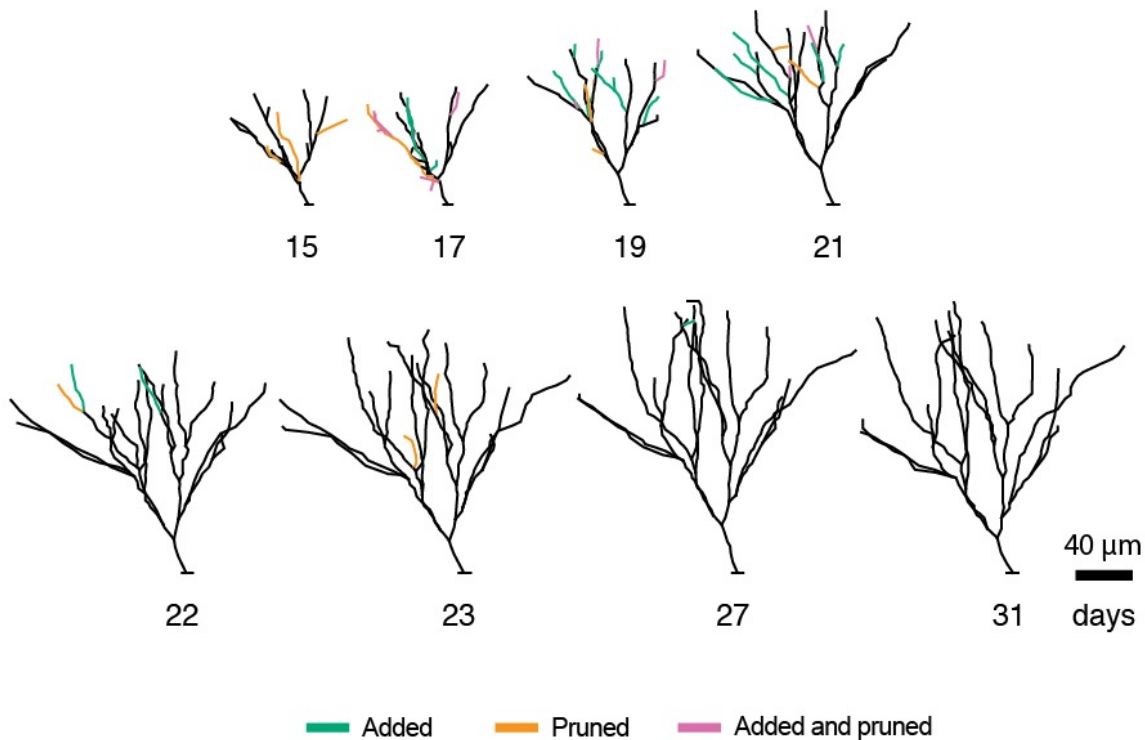

"We were surprised by the extent of the pruning we saw," says senior author Rusty Gage, a professor in Salk's Laboratory of Genetics and holder of the Vi and John Adler Chair for Research on Age-Related Neurodegenerative Disease.

While most of the brain's billions of cells are formed before birth, Gage and others previously showed that in a few select areas of the mammalian brain, stem cells develop into new neurons during adulthood. In the new study, Gage's group focused on cells in the dentate gyrus, an area deep in the brain thought to be responsible for the formation of new memories. The scientists used a new microscopy technique to observe

new cells being formed in the [dentate gyrus](#) of adult mice.

"This is the first time we've been able to image dentate neurons growing in a living animal," says Tiago Gonçalves, a research associate in the Gage lab and first author of the new paper.

Gonçalves and Gage followed—on a daily basis—the growth of neurons over several weeks. When animal were housed in environments with lots of stimuli—running wheels, plastic tubes, and domes—the new cells grew quickly, sending out dozens of branches called dendrites which receive electrical signals from surrounding neurons. When kept in empty housing, the new neurons grew slightly slower and sent out, on average, a few less dendrites. But, in both cases, the dendrites of the new cells began to be pruned back.

Salk scientists show how adult brains prune back branched connections of new neurons. Over a period of over a month, the Salk team kept track of each new neural branch, called a dendrite, on the growing neurons, as well as each dendrite that was pruned away. Here, the branches of one cell are shown -- new dendrites are in green, those pruned away are orange, and dendrites that both developed and were pruned away since the last snapshot are in pink. Credit: Salk Institute

"What was really surprising was that the cells that initially grew faster and became bigger were pruned back so that, in the end, they resembled all the other cells," says Gonçalves. He and his colleagues went on to show that changing signaling pathways could mimic some of the effects of the complex environment—cells grew more initially, but also pruned back earlier.

So why would the brain spend energy developing more dendrites than needed? The researchers suspect that the more dendrites a neuron starts with, the more flexibility it has to prune back exactly the right branches.

"The results suggest that there is significant biological pressure to maintain or retain the dendrite tree of these neurons," says Gage.

Defects in the [dendrites](#) of [neurons](#) have been linked to numerous brain disorders including schizophrenia, Alzheimer's, epilepsy and autism. Charting how the brain shapes these branches—both during embryonic development and in adulthood—may be the key to understanding mental health.

"This also has big repercussions for regenerative medicine," says Gonçalves. "Could we replace cells in this area of the brain with new

stem cells and would they develop in the same way? We don't know yet."
