

# Radiation and vaccination can magnify effects of immunotherapy

June 13 2016

---

By combining local radiation therapy and anti-cancer vaccines with checkpoint inhibitors, researchers from the University of Chicago, working with mice, were able to increase the response rate for these new immunotherapy agents.

The findings, published in the June 13, 2016 issue of the journal *Oncotarget*, showed this sequence of treatments could open up unresponsive pancreatic cancers to immune cell infiltration, often leading to immunologic control of [tumor](#) growth. They may eventually help physicians make better use of checkpoint inhibitors to treat many types of cancer.

Despite vast enthusiasm among cancer specialists about this emerging field, most patients currently have a limited response to checkpoint inhibitors. The average survival time for patients with advanced melanoma, for example, was about 25 months after starting treatment. That falls to 15 months for lung and kidney cancers, and less than eight months for some head and neck cancers.

"Our results provide a step-by-step strategy to break the immune barriers that protect aggressive tumors by converting so-called 'cold,' or non-T cell inflamed tumors, to a 'hot,' or T cell-inflamed phenotype," said study author Ralph Weichselbaum, MD, co-director of the University of Chicago Ludwig Center for Metastasis Research and chairman of Radiation and Cellular Oncology at the University. "By promoting T cell infiltration, radiation therapy improved the efficacy of tumor vaccines

and checkpoint inhibitors."

The researchers chose a difficult animal model, mice that had fragments of murine pancreatic cancer implanted in their flanks. Results from immunotherapy trials in human patients with pancreatic cancer have been dismal. The only checkpoint inhibitor to show any activity in pancreatic cancer produced a partial response in eight percent of patients.

The UChicago team chose this model because it produced "cold" tumors, cancers that were highly resistant to immunotherapy. These implanted tumors tended to have minimal infiltration with CD8+ T cells, the key players in tumor immunity, an indication that the mouse's immune system did not recognize the tumor tissue as foreign. These mice also had high expression of PD-L1 in regions surrounding the tumor. PD-L1 dampens the immune system's ability to respond. The combination of low T cell infiltration and high PD-L1 expression predicts poor survival.

Efforts to boost the immune response with a vaccine designed to provoke an [immune response](#) had little impact on tumor growth, even when paired with checkpoint blockade.

Adding local radiation therapy to the tumor vaccine, however, did enhance T cell infiltration into tumors. Adding a checkpoint blocker, after a single typical dose of radiation (20 Gray) and a vaccine tipped the balance, inhibiting [tumor growth](#) and extending survival of tumor-bearing mice.

"These results suggest that radiation stimulated the recruitment of vaccine-primed T cells while anti-PD-L1 therapy protected these T cells from local immune suppression," the authors wrote. "This may be a promising therapy."

"Our results suggest that radiation therapy could synergize with immunotherapy to convert cancers with an unfavorable cold phenotype to a more favorable hot phenotype," said Weichselbaum. "The radiation's effects may include release of cell fragments and other signals that stimulate the immune system, as well as elimination of some of the immunosuppressive factors."

The researchers acknowledge some limitations. The work was done in mice and research on cancer vaccines is still in its infancy. But they argue that the combination of local radiation and vaccination to induce T cell infiltration, followed by a checkpoint inhibitor to disable PD-L1-mediated immunosuppression could increase the odds of tumor control.

"We feel confident that our model, with further testing, can convert unresponsive "cold" cancers to something more responsive to treatment, leading to improved outcomes for more patients," Weichselbaum said. "This study, based on a very challenging animal model, opens up a new strategy that could make immunotherapy more effective for more cancer types. Intriguingly, the study demonstrates new antitumor effects of [radiation therapy](#) in addition to the direct cytotoxic effects of radiation on tumor cells."
