

# Physical activity reduces intrahepatic lipid content

October 4 2016

---

(HealthDay)—For patients with nonalcoholic fatty liver disease

(NAFLD) and underlying metabolic disorders, physical activity is associated with a reduction in intrahepatic lipid content and markers of hepatocellular injury, according to a meta-analysis published in the October issue of *Clinical Gastroenterology and Hepatology*.

Lorenzo A. Orci, M.D., Ph.D., from the University of Geneva, and colleagues conducted a meta-analysis to examine the effectiveness of exercise-based lifestyle interventions on liver-specific end points in patients with NAFLD and underlying metabolic disorders. Data were included from 28 trials.

The researchers found that independent of diet change, [physical activity](#) correlated with a significant reduction in intrahepatic lipid content (standardized mean difference,  $-0.69$ ) and with reductions in alanine aminotransferase and aspartate aminotransferase (weighted mean difference,  $-3.3$  and  $-4.85$  IU/L, respectively). Individuals with increasing body mass index were increasingly more likely to benefit from the intervention ( $P = 0.037$ ). No effect modification was seen by variables related to the intervention intensity.

"In a meta-analysis of randomized trials, we found strong evidence that physical activity reduces intrahepatic lipid content and markers of [hepatocellular injury](#) in patients with NAFLD," the authors write. "This effect correlated with baseline [body mass index](#)."
