The hungrier the mouse, the more risk it will take to grab cheese on the floor of a home with a house cat.

"But how does it make this risk-reward computation?" asks Michael Nitabach, professor of cellular and molecular physiology and professor

of genetics at Yale.

The answer for worms—and potentially mammals such as people—is that the [nervous system](#) reverses the usual flow of information from sensory input areas to higher sensory-motor integration centers, Nitabach and colleagues report Nov. 17 in the journal *Neuron*.

Nitabach's team, led by Yale graduate student D. Dipon Ghosh, compared the nervous systems of hungry and sated worms engaged in a task that requires them to cross a dangerous barrier that could kill them in order to obtain food. They found that signals that lead to the decision whether to cross this barrier act in a "top-down" fashion.

Instead of solely receiving and processing information from sensory areas, higher-order integration centers signal the [sensory areas](#) to implement the decision. This same reverse top-down flow of [information](#) occurs in the brains of human beings and other mammals, but it has not previously been linked to risk-reward decisions.

"The studies provide unprecedented insight into the detailed neural circuit computations underlying risk-reward decision-making in any animal," Nitabach said.
