Researchers at the Okinawa Institute of Science and Technology Graduate university (OIST) have developed a novel technique that stops cervical cancer cell migration. The research, published in *Chem* could open up new avenues in cancer treatment.

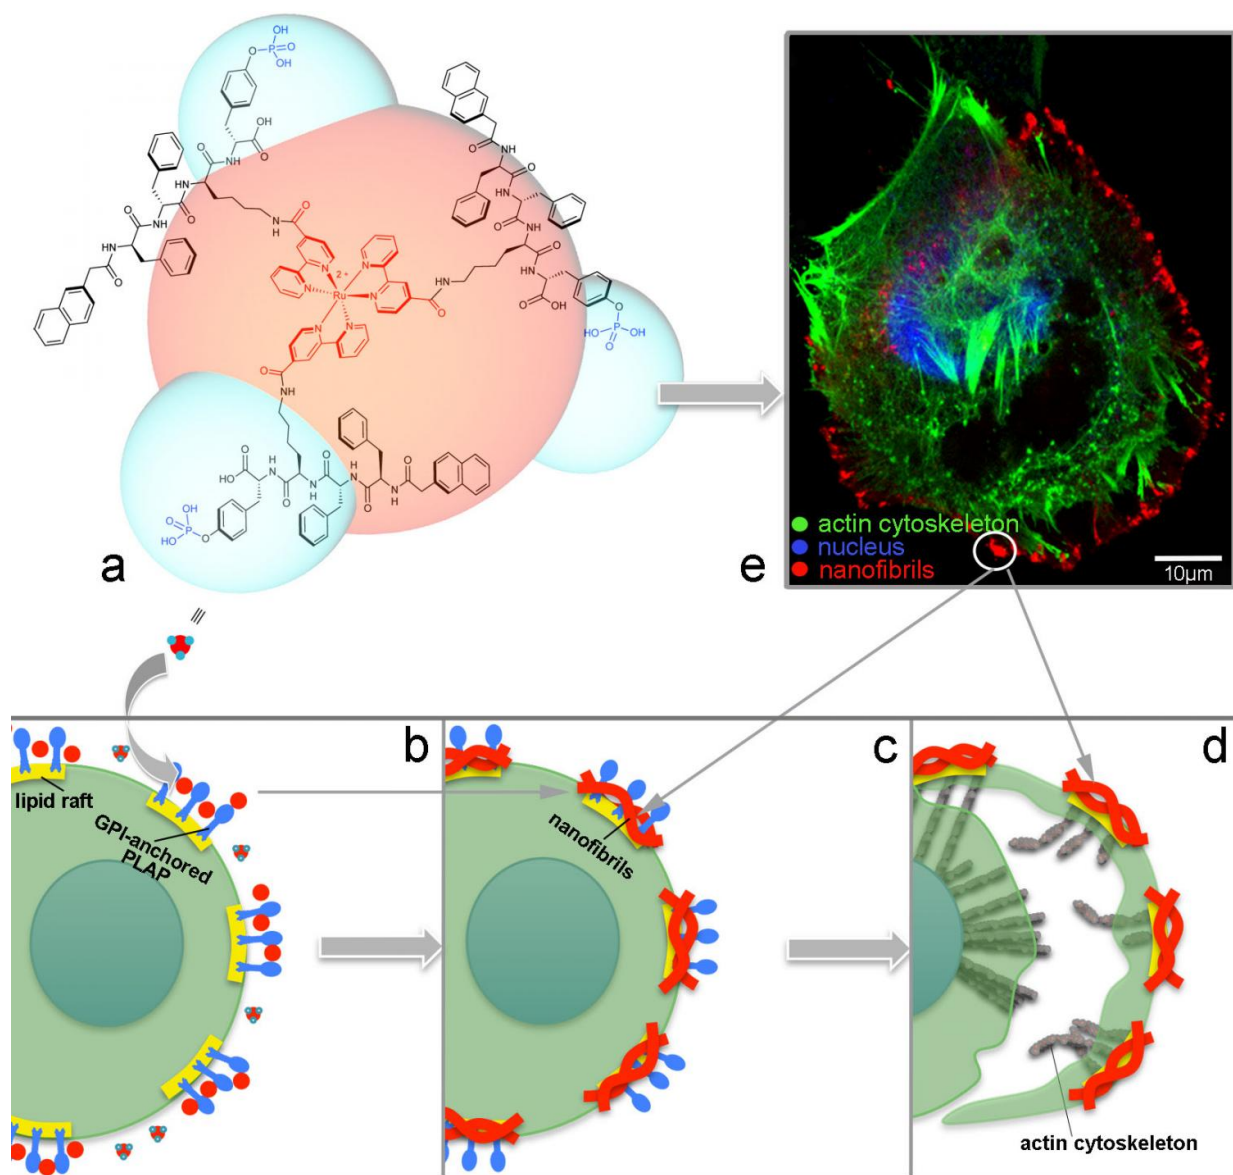

The ability of cancer cells to change position within body tissues through cell migration and invasion represents the biggest threat of cancer to human health.

Traditionally, scientists have tried to approach the problem of cancer migration by targeting molecules inside cancer cells, but finding an appropriate target has proved challenging.

"We developed a technique that targets [lipid rafts](#) on cancer cell membranes," says Professor Ye Zhang from OIST's Bioinspired Soft Matter Unit, who led the research.

Lipid rafts are free-floating domains within the cell membrane that act as platforms for communication between the outside and inside of a cell. They are associated with the cell cytoskeleton—a complex network of interlinking filaments inside the cell that is necessary for [cell migration](#)—making them viable targets for inhibiting migration.

Dr. Guanying Li and Professor Zhang worked with colleagues from OIST's Imaging and Instrument Analysis Section, as well as scientists in the SM Application Group of JEOL in Tokyo.

The cancer-busting molecule synthesized by Zhang's team (a) interacts with GPI-anchored PLAP on the lipid rafts of cervical cancer cells and undergoes self-assembly into nanofibrils (b). As the cancer cell tries to migrate, away, more nanofibrils self-assemble on other lipid rafts in the cell membrane, pinning it at the cell margin (c). As the cervical cancer continues to migrate away from the pinned regions, the opposing stretch forces cause it to rupture, killing it (d). Immunostaining of cervical cancer cells (e) enables visualization of the cell nucleus (blue), cytoskeleton (green) and self-assembled nanofibrils (red), as well as cell rupture. The team designed and synthesized a luminescent molecule that recognizes cervical cancer cells and physically stops them from migrating. The molecule consists of a ruthenium metal complex core with three self-assembly peptide building blocks attached in a three-dimensional structure.

When these building blocks interact with a cervical cancer biomarker known as glycosylphosphatidylinositol-anchored placental alkaline phosphatase, or GPI-anchored PLAP, which is located on lipid rafts, they self-assemble into nano-scale chains, or 'nanofibrils', that glue lipid rafts into large clusters. Consequently, the associated cytoskeleton components get tied up, pinning the cancer cell on the substrate and preventing it from moving at that site.

In response, the cancer cell tries to migrate away from the immobilized site, extending projections called filopodia in the new direction of migration. Lipid rafts cluster on the filopodia tips, becoming the new sites of molecule self-assembly, that results in the pinning of the cancer cell at a second site.

This process continues as the cancer cell tries to migrate away from these immobilized regions. Progressively, the cancer cell expands its body in an attempt to escape immobilization, but the cell margins remain fixed by the nanofibrils, its body is stretched flat. The opposing stretch forces cause the cell to rupture, which leads to cell death.

Professor Zhang's team were able to visualize the pinning, stretching and rupturing of cervical cancer cells by immunostaining different parts of the cells and viewing them under a confocal fluorescent microscope and a high-resolution scanning electron microscope (SEM).

"Our research opens a window in [cervical cancer](#) therapy," says Professor Zhang. "We have shown that our molecule works on [cancer cells](#) in the lab, but the next step is to see if it works on real tumors in animals. As different cancers express different biomarkers, it might be possible to modify the molecular structure of the ruthenium molecule to target different types of cancer cell."
