

New study points the way to therapy for rare cancer that targets the young

After years of rigorous research, a team of scientists has identified the

genetic engine that drives a rare form of liver cancer. The findings offer prime targets for drugs to treat the usually lethal disease, fibrolamellar hepatocellular carcinoma (FL-HCC), which mainly strikes adolescents and young adults.

Sanford Simon, who conducted the research as head of The Rockefeller University's Laboratory of Cellular Biophysics, describes the culprit as a "chimeric gene," a mutation created when two genes fuse together. These genes normally sit far apart from each other, separated by some 400,000 base pairs, the building blocks of DNA that combine to form genes.

The chimeric gene, which Simon's lab first characterized three years ago, has been found in each of the hundreds of FL-HCC patients tested for the mutation.

A disease mechanism revealed

Having confirmed the chimeric gene as a hallmark of the <u>disease</u>, Simon set out to explore if and how it may cause these malignant tumors. He worked with Scott Lowe, a <u>cancer</u> geneticist at the Memorial Sloan Kettering Cancer Center, to develop a <u>mouse model</u> of FL-HCC.

In work published this week in the *Proceedings of the National Academy of Sciences*, the scientists used CRISPR gene editing, a highly precise tool for manipulating DNA, to generate mice that carry the 400,000 basepair deletion and produce the chimeric gene. Edward Kastenhuber, a <u>graduate student</u> in Lowe's lab, found that these mice develop liver tumors that mimic the biology of the tumors found in humans with FL-HCC, suggesting that the deletion is in itself sufficient to cause the cancer—other alterations are not necessary for tumors to grow.

However, this experiment left open the question of precisely how the

deletion spurs cancer: by eliminating genes that normally would suppress the growth of tumors, or by introducing the chimeric gene. Another experiment, in which mice with the fused gene but no deletion in the genome developed tumors, proved that it's the mutation, not the missing DNA as such, that causes the disease.

With the chimeric gene firmly established as the driver of the disease, and its cellular mechanisms defined, Simon and his team—including Gadi Lalazar, of Rockefeller's Clinical Scholars Program, and graduate student David Requena—are now working to identify potential targets for drugs to treat the disease.

New concepts for therapy

Among these drug targets is a protein produced from the fused gene that belongs to a family of enzymes called kinases. These enzymes are often mutated in cancers. "In fact," Simon explains, "some of the most successful cancer therapies available, including Gleevec, act by targeting specific kinases."

The researchers showed that disruption of the fused gene's kinase activity impaired the formation of tumors in mice—a finding that has strengthened their confidence that agents aimed at targeting this activity or its consequences might be effective against FL-HCC.

The team is also studying the effects of targeting a number of cellular signaling systems that have previously been implicated in other cancers, and that speed <u>tumor</u> growth when they become overactive in FL-HCC patients. And they will be using their new mouse model as a system to test the effectiveness of new therapies prior to initiating clinical trials in patients.

Simon first became interested in FL-HCC nine years ago, when his

12-year-old daughter Elana was diagnosed with the disease. (Now 21, Elana is a senior at Harvard, and a lead author on earlier reports characterizing the genomics of the disease.) He continues to embrace the challenge the cancer presents and attributes the latest breakthroughs to an "incredible perfect storm" of advances in all of the sciences, thanks to decades of public investment in basic research.

"Here's a cancer where, five years ago, we didn't know if it was one disease or many diseases lumped together," Simon adds. "We didn't know if it was inherited or if it was due to a sporadic mutation. And now we know exactly what the driver is and how it works, and we can start designing therapeutics."
