

Researchers identify new melatonin-based molecular targets that will allow to design new drugs against Parkinson's

January 11 2018

A team of scientists led by Darío Acuña-Castroviejo, professor at the University of Granada (UGR), has published the results of a new breakthrough in molecular mechanisms of the anti-Parkinsonian activity of melatonin.

This study, published in the renowned *Plos One* journal, has been focused on the role of nitric oxide synthases, enzymes responsible for the production of nitric oxide (NO●), a neurotransmitter and neuromodulator that, when produced in excess, participates in the process of mitochondrial [damage](#) and neurodegeneration. Especially, the inducible and neuronal forms of said enzymes (iNOS and nNOS, respectively) have been studied, since they have been considered therapeutic targets for Parkinson's disease (PD).

This UGR research team has already carried out studies on PD models in cell cultures, zebrafish and mice. "With this research we clarify one of the most controversial aspects of the pathophysiology of PD and identify highly specific molecular targets for the design of new drugs to treat this disease," says the UGR professor.

The pathophysiology of PD presents three fundamental aspects: neuroinflammation, loss of dopamine, and [mitochondrial dysfunction](#). These processes lead to the death of dopaminergic neurons and the appearance of parkinsonian symptoms.

"The mitochondria plays an essential role in the cell. Until now, it was thought that the inflammatory process that occurs in PD due to the increase of iNOS and the excessive production of NO resulted in a massive entry of NO to the mitochondria. Once there, NO would induce oxidative/nitrosative damage, bioenergetic deficiency and decrease in ATP production. All this would lead to [neuronal death](#)", explains Professor Acuña.

In this study, three strains of mice were used: control group, nNOS-deficient group, and iNOS-deficient group. Thus, scientists have been able to prove that, contrary to what was thought, the mitochondrial failure that determines dopaminergic neuronal death during the development of PD is independent of those two enzymes.

Therefore, neuroinflammation and mitochondrial damage are two independent processes that occur during Parkinson's disease. "Using high resolution respirometry techniques we could also prove that the inhibition of the mitochondrial complex I activity is the primary event responsible for bioenergetic failure and the deficiency of ATP (the fuel of most cellular processes)". Therefore, "the sequence of events leading to dopaminergic neuronal death in PD begins with mitochondrial damage, continues with a process of [neuronal damage](#), it is followed by an inflammatory response or neuroinflammation, and culminates in neuronal death and loss of dopamine. In turn, neuronal death favors mitochondrial damage, thus entering a chronic vicious circle of [oxidative stress](#) that accelerates neurodegeneration", explains Acuña.

As a matter of fact, melatonin is capable of preventing all those neurodegenerative processes because its main function is to act within the mitochondria, where it restores complex I activity and the production of ATP. This neutralizes the oxidative stress and neuroinflammation that result from mitochondrial dysfunction, thus preventing neuronal [death](#).

Melatonin has proven, once again, its neuroprotective capacity and its clinical utility due to the specificity of its actions for maintaining the integrity of [mitochondrial function](#).
