

Deep brain stimulation may be promising Alzheimer's treatment

February 1 2018

(HealthDay)—For patients with Alzheimer's disease (AD), the use of

deep brain stimulation (DBS) at the ventral capsule/ventral striatum (VC/VS) region is well tolerated and is associated with less decline on the Clinical Dementia Rating-Sum of Boxes (CDR-SB), according to a study published online Jan. 30 in the *Journal of Alzheimer's Disease*.

Douglas W. Scharre, M.D., from The Ohio State University Wexner Medical Center in Columbus, and colleagues conducted a non-randomized phase I prospective open label intervention trial of three AD patients with matched comparison groups. The CDR-SB was compared for AD participants given DBS for at least 18 months at the VC/VS target to matched groups without DBS from the AD Neuroimaging Initiative cohort. In addition, over time, AD participants' serial 2-deoxy-2-[¹⁸F]fluoro-D-glucose (FDG) [positron emission tomography](#) (PET) images were compared longitudinally.

The researchers found that DBS was well tolerated by all participants, without significant adverse events. Relative to matched comparison groups, all three participants had less performance [decline](#), and two had meaningfully less decline over time on CDR-SB using score trajectory slopes. After chronic DBS at the VC/VS target, minimal changes or increased metabolism were seen on FDG-PET in frontal cortical regions.

"The first use of DBS in AD at a frontal lobe behavior regulation target (VC/VS) was well tolerated and revealed less performance decline in CDR-SB," the authors write. "Frontal network modulation to improve executive and behavioral deficits should be furthered studied in AD."
