

## Many cases of dementia may arise from noninherited DNA 'spelling mistakes'

October 15 2018

Only a small proportion of cases of dementia are thought to be inherited—the cause of the vast majority is unknown. Now, in a study published today in the journal *Nature Communications*, a team of

scientists led by researchers at the University of Cambridge believe they may have found an explanation: spontaneous errors in our DNA that arise as cells divide and reproduce.

The findings suggest that for many people with neurodegenerative diseases such as Alzheimer's <u>disease</u> and Parkinson's disease, the roots of their condition will trace back to their time as an embryo developing in the womb.

In common neurodegenerative diseases, toxic proteins build up in the brain, destroying brain <u>cells</u> and damaging brain regions, leading to symptoms including personality changes, memory loss and loss of control. Only around one in twenty patients has a family history, where genetic variants inherited from one or both parents contributes to disease risk. The cause of the majority of cases—which are thought to affect as many as one in ten people in the developed world—has remained a mystery.

A team of researchers led by Professor Patrick Chinnery from the Medical Research Council (MRC) Mitochondrial Biology Unit and the Department of Clinical Neurosciences at the University of Cambridge hypothesised that clusters of brain cells containing spontaneous genetic errors could lead to the production of misfolded proteins with the potential to spread throughout the brain, eventually leading to neurodegenerative disease.

"As the global population ages, we're seeing increasing numbers of people affected by diseases such as Alzheimer's, yet we still don't understand enough about the majority of these cases," says Professor Chinnery. "Why do some people get these diseases while others don't? We know genetics plays a part, but why do people with no family history develop the disease?"

To test their hypothesis, the researchers examined 173 tissue samples from the Newcastle Brain Tissue Resource, part of the MRC's UK Brain Banks Network. The samples came from 54 individual brains: 14 healthy individuals, 20 patients with Alzheimer's and 20 patients with Lewy body dementia, a common type of dementia estimated to affect more than 100,000 people in the UK.

The team used a new technique that allowed them to sequence 102 genes in the brain cells over 5,000 times. These included genes known to cause or predispose to common neurodegenerative diseases. They found 'somatic mutations' (spontaneous, rather than inherited, errors in DNA) in 27 out of the 54 brains, including both healthy and diseased brains.

Together, these findings suggest that the mutations would have arisen during the developmental phase—when the brain is still growing and changing—and the embryo is growing in the womb.

Combining their results with mathematical modelling, their findings suggest that 'islands' of brain cells containing these potentially important mutations are likely to be common in the general population.

"These spelling errors arise in our DNA as cells divide, and could explain why so many people develop diseases such as dementia when the individual has no family history," says Professor Chinnery. "These mutations likely form when our <u>brain</u> develops before birth—in other words, they are sat there waiting to cause problems when we are older."

"Our discovery may also explain why no two cases of Alzheimer's or Parkinson's are the same. Errors in the DNA in different patterns of <u>brain cells</u> may manifest as subtly different symptoms."

Professor Chinnery says that further research is needed to confirm whether the mutations are more common in patients with dementia.

While it is too early to say whether this research will aid diagnosis or treatment this endorses the approach of pharmaceutical companies who are trying to develop new treatments for rare genetic forms of <u>neurodegenerative diseases</u>.

"The question is: how relevant are these treatments going to be for the 'common-or-garden' variety without a <u>family history</u>? Our data suggests the same genetic mechanisms could be responsible in non-inherited forms of these diseases, so these patients may benefit from the treatments being developed for the rare genetic forms."
