

How a common drug causes liver failure

October 11 2018

High doses of acetaminophen, also known as Tylenol, can damage the liver. This figure shows how acetaminophen (APAP) is broken down into a reactive compound (NAPQI) that binds covalently to proteins at cysteine residues. While this effect is well known, it does not account for all of the changes observed in acetaminophen-induced liver failure. Researchers have reported that binding by the reactive compound NAPQI activates a protein modification pathway called glutathionylation, which impairs protein function. The research illuminates early steps in a cascade of failures that can cause tissue damage, liver failure and sometimes death by acetaminophen overdose. Acetaminophen is a common pain reliever found in every pharmacy. However, it is also the No. 1 cause of acute liver failure in the United States. In the liver, acetaminophen is converted into a new compound that covalently binds to proteins at an amino acid called cysteine. These covalent binding events are known to contribute to the toxicity of acetaminophen, but they cannot fully account for its role in liver failure. The compound is known to impair the activity of mitochondria, the cell's energy supplier, but does not bind directly to some of the enzymes in mitochondria whose activity it affects. Now researchers have found a new way that the breakdown product affects proteins in the liver.

James Chun Yip Chan and colleagues at the National University of Singapore examined glutathionylation, a post-translational modification made to cysteine residues, in response to [acetaminophen toxicity](#). In a study published in the journal *Molecular & Cellular Proteomics*, the researchers reported a new proteomic approach to isolate and identify glutathionylated proteins and applied it in cells treated with acetaminophen. They found that an acetaminophen breakdown product can cause glutathionylation, suggesting a new mechanism for the damage the drug causes.

Usually, glutathione is added to cysteine residues to protect them from damage by oxygen under stressful conditions. Chan and colleagues showed that acetaminophen and its breakdown product activate glutathionylation in a dose-dependent way. The modification affects proteins involved in mitochondrial fuel uptake and energy production, leading to metabolic dysfunction and other effects linked to acetaminophen toxicity. This research helps explain the drug's toxicity at high doses, especially among enzymes that are impaired by acetaminophen treatment without binding directly to the drug or its metabolites. The findings may also apply to other drugs with similar structures.
