

Study finds exercise benefits brains, changes blood flow in older adults

January 31 2019

'We are seeing that exercise can impact biomarkers of brain function in a way that might protect people by preventing or postponing the onset of dementia.' -- University of Maryland Associate Professor J. Carson Smith Credit: John Consoli, University of Maryland

Exercise training alters brain blood flow and improves cognitive performance in older adults, though not in the way you might think. A

new study published by University of Maryland School of Public Health researchers in the *Journal of Alzheimer's Disease* showed that exercise was associated with improved brain function in a group of adults diagnosed with mild cognitive impairment (MCI) and a decrease in the blood flow in key brain regions.

"A reduction in blood flow may seem a little contrary to what you would assume happens after going on an exercise program," explained Dr. J. Carson Smith, associate professor in the Department of Kinesiology. "But after 12-weeks of exercise, adults with MCI experienced decreases in cerebral blood flow. They simultaneously improved significantly in their scores on cognitive tests."

Dr. Smith explains that for those beginning to experience subtle memory loss, the brain is in "crisis mode" and may try to compensate for the inability to function optimally by increasing cerebral blood flow. While elevated cerebral blood flow is usually considered beneficial to brain function, there is evidence to suggest it may actually be a harbinger of further memory loss in those diagnosed with MCI. The results of the study by Dr. Smith and his team suggest exercise may have the potential to reduce this compensatory blood flow and improve cognitive efficiency in those in the very early stages of Alzheimer's Disease.

A control group of cognitively healthy [older adults](#) without [mild cognitive impairment](#) also underwent the exercise training program, consisting of four 30-minute sessions of moderate-intensity treadmill walking per week. But the program yielded different responses from each group.

Unlike the group with MCI, whose exercise training decreased cerebral blood flow, the [exercise training](#) increased cerebral blood flow in the frontal cortex in the healthy group after 12 weeks. Their performance on the cognitive tests also significantly improved, as was observed the MCI

group.

For this study, changes in cerebral [blood flow](#) were measured in specific brain regions that are known to be involved in the pathogenesis of Alzheimer's disease, including the insula (involved in perception, motor control, self-awareness, cognitive functioning), the [anterior cingulate cortex](#) (involved in decision making , anticipation, impulse control and emotion) and the inferior frontal gyrus (involved in language processing and speech).

Specifically, among those with MCI, the decreased [cerebral blood flow](#) in the left insula and in the left anterior cingulate cortex were strongly correlated with improved performance on a word association test used to measure memory and cognitive health.

A previous publication from this study led by Dr. Smith focused on how the exercise intervention influenced changes in the brain's neural networks known to be associated with memory loss and amyloid accumulation, which are both signs of MCI and Alzheimer's.

"Our findings provide evidence that exercise can improve brain function in people who already have cognitive decline," Dr. Smith said optimistically. "We have an interest in targeting people who are at increased risk for developing Alzheimer's earlier in the disease process. We are seeing that exercise can impact biomarkers of [brain function](#) in a way that might protect people by preventing or postponing the onset of dementia."
