

New breakthroughs for muscular dystrophy research

February 15 2019, by Rachel Hatch

A *C. elegans* worm expresses a calcium indicator molecule in its muscles. When muscles contract and calcium is released, this molecule (called GCaMP) binds to it and emits light. This allows scientists to measure how hard the muscles of the animals are working, and how fast calcium is released and cleared from the cell.

A new study by Illinois State University's Andrés Vidal-Gadea is breaking ground in the field of muscular dystrophy research.

Published Tuesday in *Proceedings of The National Academy of Science* of the United States of America, the study lays out the success of Vidal-Gadea's lab in mirroring symptoms of muscular dystrophy in an animal, the *C. elegans* worm.

"That had been a big snag in this research field," said Vidal-Gadea, who noted the [worms](#) share two-thirds of the same genes as humans, and build muscles the same way. "No animal gets as sick as we do, so when you try to study this disease and the animal doesn't get as sick, you cannot make a lot of progress when studying this disease." The lab managed to grow the worms where the gene was "broken" with muscular dystrophy the same as it is in humans.

The innovative study, which is funded through the National Institutes of Health, also pioneered new methods of studying *C. elegans* in more natural environments, all with the aim of seeing if exercise produces long-term beneficial effects for muscular dystrophy patients.

"Rather than just grown on top of a petri plate, as is tradition, we could watch them burrow," said Vidal-Gadea, an assistant professor of molecular neuroethology, who employs the worms in a variety of neurological studies. The new method brought out the phenotype of the disease—or led to the worms displaying the illness.

Students in the lab altered the exercise regime for worms to mimic different activities. Some *C. elegans* simply sat near food. Others swam to mirror high-frequency/low impact exercise such as jogging. Still others burrowed through gelatin to give the same effect as weight-lifting. Over time, worms that exercised built up muscles at different levels, but saw no change in the length of life or in the course of disease.

"It's unfortunate, but our interpretation is that the exercise tested does not impact the course of the disease," said Vidal-Gadea.

The work touches close to home for Vidal-Gadea, who worked with patients with muscular dystrophy when he was an [undergraduate student](#) studying at the University of Victoria in British Columbia, Canada. At times, clients who would try different methods of exercise could end up worse off than when they started. "That was brutal to see. They were trading their health for a chance to get better, but there is nothing in the literature that is conclusive about what helps," he said.

The failure is not in the [exercise](#) itself, but how the disease operates, noted Vidal-Gadea. He compared muscles to the engine of a car that provide force. "You can build up the engine and gather more force," he said. "But the problem isn't the engine, it's in how the force is transmitted. So just building muscles alone is like trying to put a Formula 1 engine into a little Volkswagen bug when the transmission is broken. You might just tear your car apart. Now, if you only look at some of the parameters like maximal RPMs of the engine, you may be led to believe that the treatment helped."

The three-year study will also help scientists better understand the chain of events when humans develop muscular dystrophy, and the symptoms that arise. "We know that when people get muscular dystrophy, the gene is broken and muscles die," said Vidal-Gadea, "but there are a lot of things that happen in between that we don't know." He added that piecing together the chain will give scientists a view into what damage is caused by the disease and what is sparked by the muscles trying to fight back.

One step along the chain Vidal-Gadea's team examined was the amount of calcium released in the muscles of those battling Duchenne muscular dystrophy. "There is a build-up of calcium that is released when the muscles contract," said Vidal-Gadea. "For those who have muscular dystrophy, the amount of calcium released can be notably higher." The study examined the changes in calcium as the worms moved. "We can

begin to see where and when the calcium in the muscles becomes dysregulated. This gives us potential targets to go after to make improvements for those with [muscular dystrophy](#).

Even more striking, in several cases, the students were able to prevent dystrophic animals from developing signs of sickness. "It was very few cases, and the illness did not go away, but the *C. elegans* did not show any symptoms of it in their actions," said Vidal-Gadea. "Our next steps will be to explore what chain of events might have led to the reversal."

The lab will continue to work with the help of NIH funding. Students involved include graduate, undergraduate, and [high school students](#), along with collaboration with individuals at the University of Illinois and the Fred Hutch Center in Seattle, Washington. "We use a wide array of techniques that can be complicated," said Vidal-Gadea. "The work these students are doing is propelling them in terms of research and moving toward their goals of medical school or lab experience."
