

How the immune system protects us against bowel cancer

Researchers at Universitätsmedizin Berlin have discovered a protective mechanism which is used by the body to protect intestinal stem cells from turning cancerous. The body's innate immune system was found to play a pivotal role in this regard. The researchers were able to demonstrate that, rather than having a purely defensive role, the immune system is crucial in maintaining a healthy body. The study has been published in the renowned scientific journal *Nature*.

Inside our bowels, there is a meeting of two worlds. This is where the cells of our intestinal cell walls meet foreign materials, such as bacteria, foodstuffs, and the breakdown products of digestion. Both of these worlds—that of our bodies and that of the outside world—are in direct contact, continually exchanging information. This direct contact is of crucial importance to our bodies, as many of the [environmental factors](#) we are exposed to (such as certain types of bacteria or essential nutrients) are beneficial or even vital to our health. However, contact with the environment can also have a negative impact on our bodies. Certain foreign substances, for instance, can trigger genetic changes inside the [epithelial cells](#) which line our intestinal walls. The accumulation of this type of DNA damage, particularly when it occurs inside epithelial stem cells, can lead to bowel cancer.

To prevent this progression to cancer, cells have the capacity to repair DNA damage. Where damage is too extensive, they can commit 'altruistic cell suicide' (also known as apoptosis). Until now, scientists had assumed that stem cells triggered this repair mechanism independently. However, the study (led by Prof. Dr. Andreas

Diefenbach, Director of Charité's Institute of Microbiology, Infectious Diseases and Immunology, BIH-Professor in Precision Medicine and Head of the Mucosal Immunology Research Group at the German Rheumatism Research Center) comes to a different conclusion, namely that the immune system is capable of enhancing the DNA repair mechanism in damaged stem cells, thus preventing progression to bowel cancer.

Working with other researchers, Prof. Diefenbach and his team were able to show in a [mouse model](#) that cells of the innate immune system are capable of recognizing genotoxic environmental factors present in the bowel. Among these are certain glucosinolates, natural components of plants which are commonly found in many types of cabbage. Once the cells of the innate immune system detect damaging glucosinolates, they send out interleukin 22, a type of cellular messenger. This, in turn, enables the epithelial stem [cells](#) to detect potential DNA damage earlier and repair it faster. "The immune system acts like a sensor that detects genotoxic food components," explains Prof. Diefenbach. "Switching off this sensor results in a significant increase in cases of bowel cancer."

For the immunologist, these findings are not only evidence of a previously unknown regulatory system which is used by the [body](#) to protect itself against [bowel](#) cancer. It is also evidence of the fact that the immune system's functions are far more complex than that of a simple defense mechanism against pathogens. "The immune system monitors both the healthy growth and function of different organs in the body," explains Prof. Diefenbach. He and his team would like to use future research studies to explore the complex interaction between food components, intestinal flora, the intestinal wall and the [immune system](#) in greater detail. "It is here that we may find the key to why there are so many inflammatory disorders," says Prof. Diefenbach.
