In a world first, neuroscientists from the University of Glasgow have been able to construct 3-D facial models using the unique information

stored in an individual's brain when recalling the face of a familiar person.

The study, which is published today in *Nature Human Behaviour*, will be the cornerstone for greater understanding of the brain mechanisms of face identification, and could have applications for AI, gaming technology and [eyewitness testimony](#).

A team of Glasgow Scientists studied how their colleagues (14 in total) recognised the [faces](#) of four other colleagues, by determining which specific facial [information](#) they used to identify them from [memory](#).

To test their theories the researchers had volunteers compare faces which were in all points the same—same age, gender or ethnicity—except for the information that defines the essence of their identity. By doing so, the scientists designed a methodology which was able to 'crack the code' of what defines visual identity and generate it with a computer program.

The scientists then devised a method which, across many trials, led them to be able to reconstruct what information is specific to the identity of an individual in someone else's memory.

Philippe Schyns, Professor of Visual Cognition at the Institute of Neuroscience and Psychology, said: "It's difficult to understand what information people store in their memory when they recognise familiar faces. But we have developed a tool which has essentially given us a method to do just that.

"By reverse engineering the information that characterises someone's identity, and then mathematically representing it, we were then able to render it graphically."

The researchers designed a Generative Model of 3-D Face Identity, using a database of 355 3-D faces that described each face by its shape and texture. They then applied linear models to the faces to be able to extract the shape and texture for non-identity factors of sex, age and ethnicity, thereby isolating a face's unique identity information.

In the experiment, the researchers asked observers to rate the resemblance between a remembered familiar face, and randomly generated faces that shared factors of sex, age and ethnicity, but with random identity information. To [model](#) the mental representations of these familiar faces, the researchers estimated the identity components of shape and texture from the memory of each observer.

As well as identification, the scientists were then able to use the [mathematical model](#) to generate new faces by taking the [identity](#) information unique to the [familiar faces](#) and combining it with a change their age, sex, ethnicity or a combination of those factors.

The paper, "Modelling Face Memory Reveals Task-Generalizable Representations," is published in *Nature Human Behaviour*.
