

Study reveals missing link in mechanisms underlying fight-or-flight response

January 23 2020, by Kevin Jiang

We've all felt the effects of an adrenaline rush. Faced with danger, real or perceived, the heart beats faster, breathing quickens and muscles tighten as the body prepares to fight a threat or flee from it.

The role of adrenaline in triggering the fight-or-flight response is one of the most well-studied phenomena in biology. However, the precise molecular mechanisms for how the hormone stimulates cardiac function have remained unclear.

Now, researchers from Harvard Medical School and Columbia University have solved the long-standing mystery of how adrenaline regulates a key class of membrane proteins—voltage-gated [calcium channels](#)—that are responsible for initiating the contraction of heart [cells](#).

Using a technique known as proximity proteomics, the team discovered that under normal conditions, a protein called Rad dampens the activity of calcium channels. When heart cells are exposed to a drug mimicking adrenaline, Rad releases from the [channel](#), leading to greater activity and stronger beating of the heart.

The findings, published in *Nature* on Jan. 22, provide a mechanistic description of how adrenaline stimulates the heart and present new targets for cardiovascular drug discovery.

In particular, the authors say, the results could open new paths for the development of drugs as effective as, but potentially safer than, beta-blockers—a widely prescribed class of medications that block the effects of adrenaline to address cardiovascular issues such as high blood pressure.

"Under normal circumstances, calcium channels in the heart work efficiently, but they have a handbrake on in the form of the protein Rad," said Marian Kalocsay, instructor in [systems biology](#) and director of proteomics in the Laboratory of Systems Pharmacology at HMS and co-corresponding author with Steven Marx, professor of medicine at Columbia University Vagelos College of Physicians and Surgeons.

"When we need full power, adrenaline releases this handbrake so that these channels open faster and give the boost needed to fight or flee from danger," Kalocsay said.

The findings, the authors noted, yield insights that could be of interest for researchers in other fields, especially neuroscience, as voltage-gated calcium channels play a central role in neuronal excitation.

Missing link

As a primary driver of cardiac function, voltage-gated calcium channels are embedded in the membranes of cardiomyocytes—the cells that constitute heart muscle. These channels open and close to control the flow of calcium ions into the cell. When open, the influx of calcium initiates heart contraction.

Adrenaline stimulates voltage-gated calcium channels by activating a protein known as PKA, which in turn activates the channel. It was thought for decades that PKA does this by altering specific regions on the channel known as PKA phosphorylation sites, but a growing body of evidence indicated that this hypothesis was incorrect.

In the current study, the team genetically engineered mice with cardiomyocytes lacking PKA phosphorylation sites. They found that modified cells continued to respond when stimulated by an adrenaline-like drug, suggesting the presence of an unknown factor.

The researchers turned to proximity proteomics, a technique that allowed them to identify nearly every protein located near voltage-gated calcium channels, at a distance of around 20 nanometers, or 10 times the width of a strand of DNA. They profiled proteins in both mouse cardiomyocytes and intact, functional mouse hearts, before and after exposure to an adrenaline-like drug.

The analyses revealed that only one protein, Rad, consistently exhibited a major change in levels after adrenaline exposure, decreasing by around 30 percent to 50 percent in the neighborhood of the channels.

To further investigate, the researchers recreated this signaling system outside of heart cells, by expressing both Rad and voltage-gated calcium channels in human kidney cells, which normally do not contain either. When cells with both Rad and calcium channels were exposed to an adrenaline-like drug, channel activity increased dramatically. Cells without Rad had little to no response. Until now, it had not been possible to reproduce calcium channel modulation in this manner because Rad as a critical ingredient was missing, the authors said.

Additional experiments confirmed that Rad functions to dampen the activity of voltage-gated calcium channels. When given an adrenaline-like signal, PKA modifies regions of the Rad protein, which then dissociates from the channel to increase its activity.

Simple, elegant

The discovery opens new avenues of research as voltage-gated calcium channels play central roles in a wide range of organ functions.

In addition, the techniques used in the study, including quantitative mass spectrometry and tandem mass tagging—pioneered by study co-author Steven Gygi, professor of cell biology at the Blavatnik Institute at HMS—allow researchers to probe protein biology and interactions with unprecedented precision, including protein behavior in functional, intact organs, as was the case in this study.

The findings can inform new therapeutic approaches, the authors said. For example, disrupting the interaction between Rad and the calcium channel could enhance heart function by increasing calcium flow into

cells. Conversely, blocking the modification of Rad by PKA may represent an alternative, more specific, strategy than beta-blockers to reduce calcium influx into the [heart](#).

"It's exciting to finally solve how the cardiac [calcium](#) channel is stimulated in the fight-or-flight response. This mystery has remained stubbornly elusive for over 40 years," said Marx. "In the end, the underlying mechanism turned out to be simple and elegant. With this information, we can potentially design novel therapeutics targeting this pathway for the treatment of cardiac diseases."
