

Study finds no overall survival benefit, but improved quality of life with talazoparib in BRCA-mutated breast cancer

April 27 2020

New data from the Phase III EMBRACA trial led by researchers at The University of Texas MD Anderson Cancer Center found the PARP inhibitor talazoparib did not demonstrate a statistically significant overall

survival (OS) benefit for patients with metastatic HER2-negative breast cancer and mutations in the BRCA1/2 genes. Most patients included in the study went on to receive subsequent systemic therapies, which may have affected the survival outcome analysis. The research confirmed previous results showing talazoparib improved patient reported quality-of-life measures over available chemotherapies and had a tolerable safety profile.

The secondary endpoint results from the EMBRACA trial were presented today at the American Association for Cancer Research (AACR) [annual meeting](#) by Jennifer Litton, M.D., professor of Breast Medical Oncology. The primary analysis results previously were published in the *New England Journal of Medicine* and found that [patients](#) treated with talazoparib had significantly prolonged progression-free survival (PFS) when compared with chemotherapy, with a median PFS of 8.6 months versus 5.6 months, respectively. This led to Food and Drug Administration approval for talazoparib in 2018.

EMBRACA is the largest trial of PARP monotherapy to date in patients with germline BRCA-mutated HER2-negative advanced breast cancer. The final OS analysis was performed using the intent-to-treat population after 324 deaths had been observed. After a median follow-up of 44.9 months for talazoparib and 36.8 months for chemotherapy, 216 patients in the talazoparib group and 108 patients in the chemotherapy group had died. The effect of treatment with talazoparib also was similar regardless of BRCA status.

"Overall survival is always an important endpoint, but also a challenge for metastatic breast cancer patients as there are many treatment options available," said Litton. "Many of these patients also received subsequent therapies, including PARP inhibitors and platinum-based therapies, which could have potentially influenced these results."

Mutations in the BRCA1/2 genes, which account for 5 to 10% of all breast cancers, cause defects in normal DNA damage repair. PARP inhibitors block an additional DNA repair pathway, and the anti-tumor effects of PARP inhibitors can be intensified in patients with BRCA mutations. Talazoparib works by not only inhibiting the PARP enzyme, but by trapping the enzyme on DNA to further prevent DNA repair.

The international Phase III clinical trial, EMBRACA, enrolled 431 patients with locally advanced or metastatic and hereditary BRCA1/2 gene mutations. Patients with HER2-positive disease were excluded as there are approved targeted therapies for those cancers. Patients were allowed up to three previous chemotherapies, including platinum-based therapies.

Participants were randomized 2:1 to receive either talazoparib (287) or physician's choice of treatment (PCT) of single-agent therapy (144), either capecitabine, eribulin, gemcitabine or vinorelbine. Fifty-four percent of participants had HR+ disease and 46% had triple negative breast cancer; BRCA1 and BRCA2 mutations were split at 45 and 55%, respectively.

Almost half of patients in the talazoparib group received a subsequent PARP inhibitor or platinum therapy compared with almost 60% of patients in the chemotherapy group. When looking at PARP inhibitors specifically, approximately a third of patients in the chemotherapy group received a subsequent PARP inhibitor, which became increasingly available to patients either through trials or commercially during the course of this trial, compared with only 4.5% of patients who received talazoparib.

Subsequent platinum therapy was received by around 46% of patients in the talazoparib group compared with approximately 42% of patients in the chemotherapy group.

Interpretation of the OS results may have been confounded by subsequent treatments, so two sensitivity analyses accounting for subsequent PARP inhibitor and/or platinum therapy were carried out.

The analysis suggests that the OS analysis underestimated the treatment benefit of talazoparib.

Patient-reported quality-of-life measures revealed a prolonged time to deterioration of overall health, 26.3 months in the talazoparib arm compared to 6.7 months for the chemotherapy arm.

"Talazoparib remains an option for patients with advanced breast cancer and a germline BRCA mutation due to its improvements in progression free survival," said Litton "Other advantages include it being an oral once-daily option, as well as the demonstrated improvements in quality of life for metastatic breast [cancer](#) patients."

Grade 3-4 hematological adverse events (AEs) occurred in 56.6% of patients receiving talazoparib and 38.9% of those on chemotherapy. Most grade 3-4 AEs reported in the talazoparib group were hematologic and most were successfully managed by supportive care and dose modifications. The most common hematologic AE in patients receiving talazoparib was anemia, which was reported in 54.9% of patients receiving talazoparib compared with 19.0% of patients receiving chemotherapy.

Correlative studies currently are underway and analysis using the EMBRACA population to explore the effect of tumor BRCA zygosity and genomic loss-of-heterozygosity on efficacy outcomes also is being presented at AACR's annual meeting by Lida Mina, M.D., associate director of Breast Programs at Banner MD Anderson Cancer Center.
