

Once bitten, twice shy: Researchers explore the neurology of why one bad curry could put us off for life

A negative experience with food usually leaves us unable to stomach the thought of eating that particular dish again. Using sugar-loving snails as

models, researchers at the University of Sussex believe these bad experiences could be causing a switch in our brains, which impacts our future eating habits.

Like many other animals, snails like sugar and usually start feeding on it as soon as it is presented to them. But through aversive training which involved tapping the snails gently on the head when sugar appeared, the snails' behavior was altered and they refused to feed on the sugar, even when hungry.

When the team of Sussex Neuroscience researchers led by Dr. Ildiko Kemenes looked a little closer, they discovered a neuronal mechanism that effectively reversed the snails' usual response to sugar after the conditioning training had taken place.

Dr. Ildiko Kemenes, Reader in Neuroscience in the University of Sussex's School of Life Sciences, explained: "There's a neuron in the snail's [brain](#) which normally suppresses the feeding circuit. This is important, as the network is prone to becoming spontaneously activated, even in the absence of any food. By suppressing the feeding circuit, it ensures that the snail doesn't just eat everything and anything. But when sugar or other food stimulus is present, this neuron becomes inhibited so that feeding can commence.

"After the aversive training, we found that this neuron reverses its electrical response to sugar and becomes excited instead of inhibited by it. Effectively, a switch has been flipped in the brain which means the snail no longer eats the sugar when presented with it, because sugar now suppresses rather than activates feeding."

When researchers presented the trained snails with a piece of cucumber instead, they found that the animal was still happy to eat the healthy option—showing that the taps were associated with only the particular

type of food they were trained to reject.

George Kemenes, Professor of Neuroscience at the University of Sussex and a senior member of the investigator team, added: "Snails provide us with a similar yet exceptionally basic model of how human brains work.

"The effect of the inhibitory neuron which suppresses the feeding circuit in the snail is quite similar to how, in the human brain, cortical networks are under inhibitory control to avoid 'runaway' activation which may lead to overeating resulting in obesity.

"In our research, the [negative experience](#) the snail had with the sugar could be likened to eating a bad takeaway curry which then puts us off that particular dish in future.

"We believe that in a [human brain](#), a similar switch could be happening where particular groups of [neurons](#) reverse their activity in line with the negative association of a particular [food](#). "

The research, funded by the Biotechnology and Biological Sciences Research Council (BBSRC) and published in *Current Biology*, also revealed that when the neuron was removed entirely from trained snails, they returned to eating sugar again.

Dr. Ildiko Kemenes said: "This suggests that the neuron is necessary for the expression of the learned behavior and for altering the response to sugar.

"However, we cannot rule out that the [sugar](#)-activated sensory pathway also undergoes some changes, so we don't make the assumption that this is all that's happening in the brain."
