

New cancer immunotherapy recruits help from lymphatic vessels

March 24 2021

Immunotherapy, which recruits the body's own immune system to attack cancer, has given many cancer patients a new avenue to treat the disease.

But many [cancer](#) immunotherapy treatments can be expensive, have

devastating side effects, and only work in a fraction of patients.

Researchers at the Pritzker School of Molecular Engineering at the University of Chicago have developed a new therapeutic vaccine that uses a patient's own [tumor cells](#) to train their immune system to find and kill cancer.

The vaccine, which is injected into the skin just like a traditional vaccine, stopped melanoma [tumor](#) growth in mouse models. It even worked long-term, destroying new tumors long after the therapy was given.

The results were published March 24 in the journal *Science Advances*.

"This is a new strategy for immunotherapy," said Prof. Melody Swartz, who led the research. "It has the potential to be more efficacious, less expensive and much safer than many other immunotherapies. It is truly personalized medicine that has the potential to overcome many issues that arise with other treatments."

Recruiting a broad immune response

In many ways, the vaccine works like a traditional flu vaccine: it uses a less-potent version of the pathogen (here, a patient's own [cancer cells](#), which are lethally irradiated before injection) to train the immune system to fight the disease.

However, rather than a preventive measure, this is a therapeutic vaccine, meaning it activates the immune system to destroy cancer cells anywhere in the body. To create it, Swartz and her team used melanoma cells from mice and then engineered them to secrete vascular endothelial growth factor C (VEGF-C).

VEGF-C causes tumors to strongly associate with the body's lymphatic system, which is normally considered bad for the patient, since it can promote metastasis. But the team recently found that when tumors activate surrounding lymphatic vessels, they are much more responsive to immunotherapy and promote "bystander" T cell activation, leading to a more robust and long-lasting immune response.

The team then had to figure out how to harness the benefits of lymphatic activation in a therapeutic strategy while avoiding the potential risks of metastasis.

'Training' the immune system

Maria Stella Sasso, a postdoctoral fellow and first author of the paper, tested many different strategies before settling on the vaccine approach, which allowed immune "training" in a site distant from the actual tumor.

The strategy of using a patient's own irradiated tumor cells in a therapeutic vaccine had previously been established by Glenn Dranoff and colleagues at the Novartis Institutes for BioMedical Research, who developed GVAX, a cancer vaccine that has been shown safe in clinical trials. Sasso decided to try this approach with VEGF-C rather than the cytokine used in GVAX. She dubbed the strategy "VEGF-C-vax."

After engineering the cells to express VEGF-C, the research team irradiated them, so they would die within a few weeks. When they injected the cells back into the skin of mice, they found that the dying tumor cells could attract and activate the immune cells, which then could recognize and kill the actual tumor cells growing on the opposite side of the mouse. Since each tumor has its own unique signature of hundreds of molecules that the immune system can recognize, the [vaccine](#) promoted a broad, robust immune response.

That led to the prevention of tumor growth in all of the mice. It also led to immunological memory, preventing new tumor growth when tumor cells were re-introduced 10 months later.

"This shows that the therapy may provide long-term efficacy against metastasis and relapse," said Swartz, William B. Ogden Professor of Molecular Engineering.

Potential therapy for many types of cancers

Conceptually, this is the first strategy to exploit the benefits of local lymphatic vessel activation for more robust and specific [immune response](#) against tumor cells.

Unlike immunotherapeutic strategies that stimulate the [immune system](#) in a general way, such as checkpoint blockade or the many cytokines currently in preclinical development, this new immunotherapy activates only tumor-specific immune cells. Theoretically, this would avoid common side effects of immune stimulants, including immunotoxicity and even death.

And while many other cancer immunotherapies, such as CAR-T cell therapy, are tumor-specific, these strategies only work against tumor cells that express specific pre-identified tumor markers called antigens. Cancer cells can eventually overcome such treatments by shedding these markers or mutating, for example.

VEGFC-vax, however, can train immune [cells](#) to recognize a large number and variety of tumor-specific antigens. More importantly, these antigens do not need to be identified ahead of time.

The researchers are working to test this strategy on breast and colon cancers and think it could theoretically work on any type of cancer. They

hope to ultimately take this therapy to clinical trials.

"We think this has huge promise for the future of personalized cancer immunotherapy," Swartz said.
