A global study, co-led by University of Galway, into causes of stroke has found that high and moderate alcohol consumption was associated with

increased odds of stroke.

The study also found that there was no link between low level drinking and [stroke](#).

The INTERSTROKE research looked at the [alcohol](#) consumption of almost 26,000 people worldwide, of which one quarter were current drinkers, and two-thirds were teetotal.

The study involved people from a range of ethnic backgrounds in 27 countries, including Ireland and the UK.

The findings have been published in *Neurology*.

Professor Martin O'Donnell, Professor of Neurovascular Medicine at University of Galway and Consultant Stroke Physician at Galway University Hospitals, co-led the international INTERSTROKE study in partnership with Professor Salim Yusuf from the Population Health Research Institute at McMaster University, Canada.

Professor O'Donnell says that "stroke is a leading cause of death and disability globally. Each year, approximately 7,500 Irish people have a stroke, and around 2,000 of these people die. An estimated 30,000 people in Ireland are living with disabilities as a result of stroke. The INTERSTROKE study was designed to look at the key risk factors for stroke in different regions of the world, to inform approaches to population-level prevention. In this paper, we focused on the role of alcohol intake and stroke risk."

"While high alcohol intake is known to increase stroke risk, there is some uncertainty about whether low-moderate alcohol intake affects stroke risk and whether the association of alcohol intake with stroke varies by region and population."

This study explored these associations in a large scale across 27 countries.

Stroke can occur due to clot (ischemic) or bleeding (intracerebral hemorrhage).

Professor Andrew Smyth, Professor of Clinical Epidemiology at University of Galway, Director of the Health Research Board-Clinical Research Facility Galway and a Consultant Nephrologist at Galway University Hospitals, was the lead researcher on the study.

Professor Smyth says that "overall, our findings indicate that high and moderate intake of alcohol were associated with increased odds of stroke, while we found no convincing link between low intake and stroke."

"However, the effects of alcohol intake are complex as they are linked with socioeconomic factors such as education and many lifestyle factors including smoking, diet and physical activity. The potential impact of what is commonly classed as 'binge drinking' is important to consider. The adverse risk of having seven drinks one day per week are likely to be greater than having one drink each day per week."

"In this study we also looked at the differences between types of alcohol. Predominant beer consumption was linked with a 21% increase in risk of stroke; this was significantly higher (73%) for intracerebral hemorrhage. Predominant wine consumption was not linked with risk of stroke—there was no increase or decrease. This may reflect a difference in risk by type of alcohol, or may reflect differences in the social context of consumption patterns."

Included in the INTERSTROKE research was an analysis of people who had previously been drinkers but had stopped. The study found that they

were not at increased risk of stroke.

Other findings from this research included:

- Current drinkers were linked with a 14% increase in odds of all stroke, and 50% increase in odds of intracerebral hemorrhage (stroke due to bleeding), but no increase in risk of ischaemic stroke (stroke due to clots).
- Heavy episodic or formerly termed 'binge drinking'—defined as more than 5 drinks in one day at least once a month—was linked with a 39% increase in all stroke; 29% increase in ischaemic stroke; and 76% increase in intracerebral hemorrhage.
- High alcohol intake—defined as more than 14 drinks/week for females and more than 21 drinks/week for males—was linked with a 57% increase in stroke.

Professor Michelle Canavan, Established Professor of Older Adult Health and Consultant Geriatrician, added that "most previous research was completed in high-income countries, with limited cultural diversity whereas the global INTERSTROKE study took a different approach by including participants from high, middle and [lower income countries](#) with varying levels of education and cardiovascular risk profiles."

"Worldwide there are differences in alcohol intake by gender, age, social class, education and occupation, as well as differences in type of alcohol consumed and the pattern of drinking."

"Current drinking was linked with reduced risk of stroke in Western Europe and North America, but increased risk of stroke in India and South America. The greatest increases in stroke risk were seen for binge drinkers in South America, Africa and India and with those who have high levels of [alcohol consumption](#) in China and South East Asia. Therefore, targeted interventions to manage high intake at population

level may help reduce stroke risk particularly for males in these regions who are more likely to binge drink."
