

Maternal exposure to PFAS tied to reproductive function of male offspring

October 17 2022

There is a consistent inverse association between maternal exposure to

perfluoroalkyl and polyfluoroalkyl substances (PFAS) and semen quality in young adult male offspring, according to a study published online Oct. 5 in *Environmental Health Perspectives*.

Katia Keglberg Hærviig, Ph.D., from Copenhagen University Hospital-Bispebjerg and Frederiksberg in Denmark, and colleagues examined associations between maternal plasma PFAS levels during early pregnancy and [male offspring](#) reproductive function in adulthood. The analysis included 864 young men and first-trimester samples from their mothers.

The researchers found that for a 1-unit increase in the weighted quantile sum index, combined maternal PFAS exposure was associated with lower sperm concentration, lower total sperm count, and a higher proportion of nonprogressive and immotile sperm in the young men. There was variance noted in the strength of associations for different PFAS; however, perfluoroheptanoic acid was identified as the main contributor in the analyses of all three outcomes despite the low concentration. There was no association between exposure to maternal PFAS and testicular volume or reproductive hormones.

"A man's reproductive capacity is largely defined in the first trimester of pregnancy when the testicles are developed," a coauthor said in a statement. "It makes sense that exposure to substances that mimic and interfere with the hormones involved in this delicate process can disrupt [normal development](#) and have consequences for semen quality later in life."

One author disclosed financial ties to the pharmaceutical industry.
