When we use our working memory, we temporarily retain information in our brain. For instance, you are able to comprehend this sentence because you are briefly storing in working memory each of the words
you are reading until you put them together to form the meaning of the sentence. The importance of working memory to many of our cognitive abilities is well known, but less clear are the neurological machinations driving this process.

A team of researchers has now demonstrated that the key to understanding working memory relies not only on what one is storing in memory, but also why. This is the "working" part of working memory, which emphasizes the purpose of storing something in the first place.

"We now know that our visual memories are not simply what one has just seen, but, instead, are the result of the neural codes dynamically evolving to incorporate how you intend to use that information in the future," explains Clayton Curtis, a professor of psychology and neural science at New York University and the senior author of the paper, which appears in the journal *Current Biology*.

Specifically, the study focuses on both how we store the visual properties of our memories in the occipital lobe, where our visual system resides, and on how the neural codes that store those memories change over time as people begin to prepare a response that depends on the memory. In the study, the response simply required people to look where they remembered an object that disappeared several seconds ago.

"The research makes it clear that memory codes can simultaneously contain information about what we remember seeing and about the future behavior that depends on those visual memories," notes Hsin-Hung Li, a New York University postdoctoral researcher and the paper's lead author. "This means the neural dynamics driving our working memory result from reformatting memories into forms that are closer to later behaviors that rely on visual memories."

Textbook theories state that the storage codes for our working memory
are stable over time. This means that the pattern of neural activity that stores a given visual memory is the same as when it was first seen and encoded—whether it is a second later or 10 seconds later. These patterns of neural activity store **visual memories**, providing a bridge across time between a past stimulus and a future memory guided response.

However, recent studies of animals indicate that these neural patterns are much more dynamic—in fact, the memory codes are not stable and, instead, appear to change over time in puzzling ways.

To explore this, Li and Curtis, who previously **uncovered** how our working memory is formatted in the brain, devised innovative methods to both measure changing neural dynamics and critically make the dynamics interpretable. To do so, they projected the complex neural measurements into a simple 2D plane, like the screen of your laptop or smartphone.

The accompanying video depicts how the pattern of neural activity evolves during a working memory trial. Initially, you can see a bump of activity encoding the briefly presented visual target (pink circle) in both **primary visual cortex** (V1) and a high-level visual area (V3AB). In V3AB, this bump remains at the target location throughout the memory delay. However in V1, a line of activity evolves during the delay between where the person is looking (pink cross) and where they will move their eyes after the delay.

The researchers believe that this line reflects the trajectory of the shift of gaze that is being rehearsed in people's minds, but has yet to be executed.

Although previous work had documented neural dynamics during working memory, the reason for why these dynamics occur had remained unknown. These new results help address this mystery. They
indicate that the dynamics reflect transformations of past sensory events—what we have just seen—into future memory guided behaviors—what we might do with the memory.

"We've now shown that mnemonic codes can simultaneously contain information about a past remembered stimulus and the subsequent behavior that depends on that stimulus," observes Curtis. "The neural dynamics of our working memory result from reformatting memories in order to align them with how we use them in the future."
