Herpes is not only unpleasant but it can, in some cases, also have dangerous complications and life-threatening consequences. In the journal *Angewandte Chemie*, a research team has now introduced a completely new approach for treating herpes. Their method is based on the inhibition of an enzyme that is needed for the release of newly formed virus particles from infected cells.

Just before an important interview or anticipated first date—always when you least need it—you feel a tingling and itching on your lip. A glance in the mirror reveals the first little blisters: [herpes](#) is back.

The majority of adults carry the instigator in their bodies because, once infected, herpes simplex type 1 viruses (HSV-1) settle into nerve ganglia. They remain in the body throughout a person's life, inactive most of the time.

If the [immune system](#) is temporarily weakened, maybe by anxiety or stress, too much sunlight, hormonal fluctuations, or a cold, an outbreak may occur. This is annoying and painful but usually harmless. However, this is not always the case: in some immunocompromised individuals or newborns there can be severe and sometimes life-threatening consequences.

Dangerous complications are also a threat if the [virus](#) infects the eyes or brain; for example, corneal herpes is one of the leading causes of infection-induced blindness. Antiviral drugs can curb herpes infections but not fully vanquish them.

A team from the University of Georgia, Athens (U.S.), the University of Illinois at Chicago (U.S.), and the University of Utrecht (Netherlands), led by Deepak Shukla and Geert-Jan Boons, has now developed an

alternative method for the treatment of herpes.

HSV-1 viruses dock to heparan sulfates, molecules that are made of many sugar (saccharide) units and are found in the [extracellular matrix](#) and plasma membranes of our cells. Once bound, the viruses can enter the cells.

In the late stages of infection the virus causes the [infected cells](#) to increase production of heparanase, an enzyme involved in the remodeling of the extracellular matrix. It splits heparan sulfates off the surface of the cell—a prerequisite for the release of the viruses newly produced in the cell so that they can spread to other cells and tissues. The idea behind this project is to block the heparanase.

The team synthesized a series of oligosaccharides that have structures like those of heparan sulfates but are not split by the heparanase enzyme. Molecules made of six or eight saccharides strongly inhibit heparanase.

By using complementary computer studies, the team was able to model the way these oligosaccharides are arranged in the enzyme's binding cavity and determine which molecular interactions are responsible for the strong binding. Treatment of corneal cells infected with HSV-1 with the active oligosaccharides had the effect of inhibiting the virally induced excretion of heparan sulfates, significantly reducing the spread of the virus.

In addition, inhibition of heparanase through the new inhibitors can impede the migration and proliferation of immortalized cells (that is, [cells](#) with uncontrolled cell growth). This enzyme has been strongly implicated in cancer metastasis, suggesting another potential application for the inhibitors in the future.
