

All the reasons you might be having night sweats—and when to see a doctor

October 16 2023, by Siobhan Banks and Linda Grosser

You've finished a workout, so you're hot and drenched with perspiration—but soon you begin to feel cool again. Later, it's a sweltering summer evening and you're finding it hard to sleep, so you kick off the covers.

Sweating is a normal part of the body's cooling system, helping to release heat and maintain optimal body temperature. But regularly waking up during the night, soaked through from excessive sweating is not.

Night sweats are [repeated episodes](#) of excessive or intense sweating at night. They are an unpleasant part of life for many people.

Many conditions and factors can trigger [night sweats](#) by changing the body's tightly regulated temperature set point, at which the body attempts to maintain its [core temperature](#). Some triggers are harmless (a hot bedroom) or even related to positive lifestyle changes (exercise). Others have an underlying cause like menopause, infection, disease or medication.

Temperature control and sweating

The hypothalamus, located in the brain, is part of the [endocrine system](#) and the temperature control center for the body. It contains [temperature sensors](#) that receive information from [nerve cells](#) (thermoreceptors) located centrally (in the organs) and peripherally in the skin.

Thermoreceptors detect changes in body temperature, sending signals back to the hypothalamus. These [signals](#) will either activate sweating to cool the body or shivering to warm the body.

Hormones and night sweats

Anyone, regardless of age or gender, can experience night sweats. But women experience night sweats more often than men, largely because menopause and associated changing [hormone levels](#) are [a leading cause](#).

Approximately 80% of women experience [hot flashes](#) (also called hot

flushes) or night sweats after [menopause](#) (when periods have ceased for 12 months) and during [perimenopause](#) (the time leading up to it).

While both [hot flashes](#) and night sweats produce a feeling of overheating, they are different experiences associated with menopause. Hot flashes occur during the day, are transient episodes of flushing and may involve sweating. Night sweats occur at night and involve an intense period of [sweating](#). Changing estrogen levels are thought to impact norepinephrine and serotonin levels, two neurotransmitters that influence [temperature regulation](#) in the hypothalamus.

Hormones also influence night sweats in men, particularly those with low [testosterone](#) levels, known as [hypogonadism](#). Around 38% of men aged 45 years or older have low testosterone [levels](#) but it can affect men at any age.

Infections, disease and medications

When fighting infection, our body temperature often [rises](#). This can stimulate sweating to cool and decrease body [temperature](#).

Minor infections like the common cold can cause night sweats. They are also a symptom of serious infections such as human immunodeficiency virus (HIV) and diseases such as [Hodgkin's](#) and [non-Hodgkin's lymphoma](#). However, night sweats are rarely the only symptom present.

Medications such as [selective serotonin reuptake inhibitors](#) (SSRIs), corticosteroids, thyroid hormone replacement and methadone can cause night sweats. These medications affect parts of the [brain](#) and neurotransmitters that control and stimulate sweating.

Regular alcohol (particularly alcohol dependence) and recreational drug use can also [increase the risk](#) of night sweats.

Stress, snoring and strenuous exercise

Night sweats are commonly reported by people with [anxiety](#).

Psychological stress activates the body's fight or flight system releasing neurotransmitters that increase heart rate, respiration, and [blood pressure](#). This causes the body to heat up, at which point it starts sweating to cool the body back down. Night sweats may also increase anxiety, causing more sweating which in turn leads to less sleep and more anxiety.

If anxiety causes night sweats and this causes distress, it's best to get up, move around and engage in a [calming routine](#), preferably in a dark or dimly lit room.

Night sweats have similarly been connected with [sleep disorders](#) like [obstructive sleep apnea](#), where the airway is repeatedly blocked during sleep and there is loud snoring. About one third of people with obstructive sleep apnea regularly [experience night sweats](#). The exact cause is undetermined but research shows it is linked with low blood oxygen levels ([hypoxemia](#)) and/or [high blood pressure](#).

People can experience night sweats after high-intensity workouts. Vigorous exercise can stimulate the thyroid, [increasing basal metabolic rate](#) and body [temperature](#) for up to [14 hours post exercise](#). So night sweats can occur even after a vigorous morning workout.

Night sweats can indicate overtraining and/or under-fueling. If not enough calories are consumed to support the increase in training, blood sugar could drop and you could experience [hypoglycaemia](#), which can cause night sweats.

When to seek help and 5 things to try

There are [numerous](#) health conditions and medications that can cause night sweats and interfere with sleep.

If night sweats are regular, distressing, interfere with sleep or are accompanied by symptoms such as fatigue or weight loss (not related to lifestyle or diet changes) talk to a doctor to help determine the cause. They might suggest alternative medications to any you're taking or recommend tests or investigations.

In the meantime, you can try the following ideas:

1. sleep in a cool room and use a fan if needed
2. don't overdress for bed. Wear breathable cotton or linen pajamas
3. choose lightweight bedding you can kick off. Avoid synthetic fibers and flannel bedding
4. consider a cooling mattress or pillow and avoid those (such as foam ones) that can limit airflow
5. avoid spicy foods, caffeine or alcohol before bed.
