

Total vascular score from PET scans prognostic in giant cell arteritis

October 3 2023, by Elana Gotkine

For patients with giant cell arteritis (GCA), a higher total vascular score

(TVS) based on ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) imaging at diagnosis is associated with a greater increase in thoracic aortic dimensions, according to a study published online Oct. 3 in the *Annals of Internal Medicine*.

Lien Moreel, M.D., from the University Hospitals Leuven in Belgium, and colleagues conducted a prospective cohort study involving 106 <u>patients</u> with GCA and FDG PET three days or less after glucocorticoid initiation. Participants underwent PET and computed tomography (CT) imaging at diagnosis and CT imaging annually for up to 10 years. The PET scans were scored in seven vascular areas and summed for a TVS. When FDG uptake was grade 2 or greater in any large vessel, PET scan results were positive.

The researchers found that patients with a positive versus a negative PET scan result had a greater increase in the diameter of the ascending aorta, the diameter of the descending aorta, and the volume of the thoracic aorta (difference in five-year progression, 1.58 mm, 1.32 mm, and 20.5 cm³, respectively). There was a positive association seen for these thoracic aortic dimensions with TVS. The risk for thoracic aortic aneurysms was higher for patients with a positive PET scan result (adjusted hazard ratio, 10.21).

"In addition to diagnostic information, performing PET imaging at diagnosis in patients with GCA may help estimate the future risk for aortic aneurysm formation," the authors write.
