

'DNA loops' in pediatric brain tumors double relapse risk, study finds

November 14 2023

The landscape of ecDNA in medulloblastoma patient tumors. **a**, Presence of ecDNA by molecular subgroup across 468 tumors from patients with medulloblastoma. **b**, A subset of recurrently ($n \geq 2$) amplified genes on ecDNA

in this patient cohort. p53 inhibitors: negative regulators of p53 pathway activity; COSMIC: genes listed as Tier 1 or Tier 2 of the COSMIC Cancer Gene Census⁶¹. **c**, Kaplan–Meier curve depicting five-year overall survival in the patient cohort stratified by the presence of ecDNA in tumors. $P = 8.6 \times 10^{-6}$. **d–f**, Kaplan–Meier curves indicating overall survival for SHH ($P = 4.8 \times 10^{-3}$) (**d**), Group 3 ($P = 0.01$) (**e**) and Group 4 ($P = 0.01$) (**f**) subgroups, stratified by ecDNA presence. P values for **c–f** were derived from two-sided log-rank test without correction for multiple hypotheses. **g**, Log hazard ratios for ecDNA status, medulloblastoma subgroup, age and sex estimated by Cox regression on overall survival. Sample size was $n = 352$ observations. Data are presented as maximum likelihood estimate (MLE) $\pm 95\%$ confidence intervals. Credit: *Nature Genetics* (2023). DOI: 10.1038/s41588-023-01551-3

A study of newly created databases of medulloblastoma has found that patients with tumors containing circular extrachromosomal DNA—loops of DNA found outside of regular chromosomes—are twice as likely to relapse and three times as likely to die within five years of diagnosis. The findings, [published](#) in *Nature Genetics*, pave the way for research that could yield new treatments for this aggressive childhood brain cancer.

"There are very few effective treatments available for medulloblastoma, and most treatments carry substantial risks of brain damage or secondary cancers," says senior author Lukas Chavez, Ph.D., a professor in the Cancer Genome and Epigenetics Program at Sanford Burnham Prebys. "There is a critical need for new therapies that minimize unwanted side effects. There is still so much we need to learn about what drives medulloblastoma at the molecular level, and this study is a step in the right direction."

There are around 350 new medulloblastoma diagnoses per year, and most of these are in children. Medulloblastoma is extremely aggressive

and often resists treatment, which involves a combination of surgery, radiation, and chemotherapy. Because medulloblastoma is relatively rare and has different subtypes, it has been difficult for researchers to discover new treatments for the disease.

"Because medulloblastoma is rare, one of the challenges of studying the cancer is compiling enough patient data to study the disease holistically," says Chavez. "Fortunately, [modern technology](#) is now democratizing [data science](#), which is transforming the way we study rare cancers."

The research team compiled a database of 465 medulloblastoma patients using a combination of publicly available data and data from patients diagnosed at Rady Children's Hospital. The analysis focused on circular extrachromosomal DNA (ecDNA), circular fragments of DNA that are outside of regular chromosomes. These DNA loops can contain hundreds of copies of cancer-causing genes and are known to be present in many cancers, but until now, their effects have not been thoroughly investigated in medulloblastoma or other childhood cancers.

"These ecDNA fragments are unique to [cancer cells](#), and understanding how and why these DNA loops form and uncovering ways to therapeutically target them is a significant goal for researchers studying cancers of all types, not just medulloblastoma," says Chavez.

Using computational tools to detect ecDNA within the patients' tumors, the study revealed that while only 18% had ecDNA, these patients were twice as likely to relapse and three times as likely to die within five years of their diagnosis.

"We're finding that the presence of ecDNA fragments has a strong association with the clinical outcomes of medulloblastoma," says Chavez.

The researchers then analyzed individual tumors, and found that even within a single [tumor](#), there was a large amount of variety in how much and what kinds of ecDNA were present in individual cells.

"The genetic variety between different cells within the same tumor could help explain why medulloblastoma is so capable of evolving to resist treatment," says Chavez. "While some tumor cells may be eliminated, others survive the treatment and continue to grow."

The researchers hope that in the future, it will be possible to find new drugs that can interfere with the effects of ecDNA, though it will take more research to discover how these drugs could work.

"We're starting to see what ecDNA does in [cancer](#), but we're still working on figuring out how it happens and what we can do to stop it," says Chavez. "While there is still a lot to learn about ecDNA, the work we've done here will help pave the way for future [medulloblastoma](#) therapies."
