A study led by Guadalupe Sabio and José Jalife at the Centro Nacional de Investigaciones Cardiovasculares (CNIC) in Madrid has identified a new signaling mechanism implicated in the development of ventricular fibrillation, a type of arrhythmia, or irregular heartbeat. The [study findings](#), published in the journal *Nature Cardiovascular Research*, offer promise of future treatment options for this life-threatening condition.

Ventricular fibrillation is the most frequent cause of sudden cardiac death. Although aging is an established risk factor for the [development](#) of cardiac [arrhythmia](#), the mechanisms underlying this connection have been hard to pin down, hindering progress toward the development of specific treatments.

The heartbeat is a cycle of regular contractions of the cardiac muscle that pump blood efficiently throughout the body. Achieving this requires the highly coordinated contraction of the cardiac muscle cells in a meticulously orchestrated pattern. With the development of an arrhythmia, the cardiac cycle speeds up and becomes irregular, with potentially life-threatening consequences.

Working with animal models, the CNIC team discovered a connection between the development of ventricular fibrillation and the activation of two key signaling proteins, the stress kinases p38 $\gamma$  and p38 $\delta$ . The link with these enzymes was independent of the sex of the animals.

This discovery opens the way to new possible intervention strategies for this condition.

When the scientists examined the hearts of old mice, they found that the activation of p38 $\gamma$  and p38 $\delta$  was increased. A similar increase in the activity of these enzymes was also observed in the hearts of mice with a genetic or pharmacologically induced predisposition to developing ventricular arrhythmias. Together, these results suggest that stress signaling via p38 $\gamma$  and p38 $\delta$  likely plays an important role in the development of this condition.

"When we found that activation of these p38 kinases was a shared feature of distinct arrhythmogenic situations, we realized that they likely play an important role that we needed to investigate," said first author Según Rafael Romero.

An in-depth analysis of this signaling pathway revealed that when these [protein kinases](#) are activated they alter the electrical properties of cardiomyocytes (the heart's muscle cells), triggering the appearance of arrhythmias. This onset of arrhythmia involves p38-mediated alterations to specific ion channels that coordinate cardiomyocyte contraction.

The scientists found that p38 $\gamma$  and p38 $\delta$  phosphorylate a receptor called [ryanodine receptor](#) 2 and another protein called SAP97, resulting in a mislocalization of the potassium ion channel Kv4.3. These [molecular changes](#) lead to premature ventricular activation and an increased susceptibility to ventricular fibrillation.

The study findings identify a promising therapeutic target for the development of new strategies to prevent sustained [ventricular fibrillation](#) and provide protection against this serious condition.
