Brain cells often cluster and grow together creating three-dimensional columns. While this pillar-like pattern of neurons is established, the exact mechanism behind its formation is still elusive. Makoto Sato's team at Kanazawa University has been closely studying this phenomenon. Their recent findings explain how molecules in the brain work in conjunction to create the architectural marvels that are the columns.

The researchers base much of their work on the Drosophila (fruit fly) due to the organism's genetic similarities to humans. In this study they focused on the visual center of the fly's brain in a region known as the medulla. This region resembles the human cerebral cortex—the primary seat of reasoning. Developing columns in the medulla were photographed in real-time to find that a protein known as Fmi was abundant in the growing stages of the fly and vanished shortly after. Fmi also partakes in a process known as planar cell polarity (PCP) which drives the spatial orientation of a cell in two-dimensional space. Thus, it was purported that PCP was also at play in the development of columns. Indeed, deactivation of PCP components resulted in impaired column formation. What's more, a new candidate, Fz2, was found to be working closely with the individual PCP components.

Fz2 is linked to a cellular pathway called Wnt signaling. A close inspection of the medulla revealed that prime regulators of the Wnt pathway, DWnt4 and DWnt10, were operational in the vicinity. When DWnt4 and DWnt10 were also disabled, a disruption of column structure in neighboring regions followed. Column construction was controlled by a complex chain of architects.
therefore, instrumental to proper spatial and structural development of the columns.

This study reveals the intertwined nature of the mechanisms that drive brain development. "[We] show that Wnt ligands globally regulate neuronal orientation and column arrangement through Fz2/planar cell polarity signaling in a three-dimensional space in the brain", summarize the researchers. These processes are key to monitoring healthy growth and tracking disorders in the developing brain.
