Brainwave-reading implant lets paralyzed man spell out 1,100 words
8 November 2022

A paralyzed man who cannot speak or type was able to spell out over 1,000 words using a neuroprosthetic device that translates his brain waves into full sentences, US researchers said Tuesday.

"Anything is possible," was one of the man's favorite phrases to spell out, said the first author of a new study on the research, Sean Metzger of the University of California San Francisco (UCSF).

Last year the team of UCSF researchers showed that a brain implant called a brain-computer interface could translate 50 very common words when the man attempted to say them in full.

In the new study, published in the journal Nature Communications, they were able to decode him silently miming the 26 letters of the phonetic alphabet.

"So if he was trying to say 'cat', he would say charlie-alpha-tango," Metzger told AFP.

A spelling interface then used language-modeling to crunch the data in real time, working out possible words or errors.

The researchers were able to decode more than 1,150 words, which represent "over 85 percent of the content in natural English sentences", the study said.

They simulated that this vocabulary could be extended to more than 9,000 words, "which is basically the number of words most people use in a year," Metzger said.

The device decoded around 29 characters a minute, with an error rate of six percent. That worked out to be around seven words a minute.

The man is referred to as BRAVO1, as the first participant of the Brain-Computer Interface Restoration of Arm and Voice trial.

Now in his late 30s, he suffered a stroke when he was 20 that left him with anarthria—the inability to speak intelligibly, though his cognitive function remained intact.

He normally communicates by using a pointer attached to a baseball cap to poke at letters on a screen.

In 2019, the researchers surgically implanted a high-density electrode on the surface of his brain, over the speech motor cortex.

Via a port embedded in his skull, they have since been able to monitor the different electrical patterns produced when he tries to say varying words or letters.

'M Unique advantage'

Metzger said that BRAVO1 "really enjoyed using this device because he's able to communicate quickly and easily with us".
One of the best parts of the study was when BRAVO1 was told to spell out "whatever he wants", Metzger said.

"I got to learn a good amount about him," said Metzger.

Among BRAVO1’s surprising comments was that "he really didn't like the food where he lives," Metzger added.

Last year a brain-computer interface developed at Stanford University was able to decode 18 words a minute when a participant imagined handwriting.

But Metzger said their speech-based approach has a "unique advantage".

The 50 commonly used words—which the participant silently speaks in full—could be used for many interactions, while rarer words could be spelled out, offering the "best of both worlds", he said.

The research, which still needs to be confirmed in other participants, is still some way off from becoming available to the thousands of people who lose the ability to talk due to strokes, accidents or disease every year.

Patrick Degenaar, a neuroprosthetics professor at the UK’s Newcastle University who was not involved in the research, hailed the "very impressive results".

Because neuroprosthetic surgery is "highly invasive and has risks", such a device would likely only be used by a very small number of people in the immediate future, he told AFP.
